Table 12-29. RASTER_CTRL Register Field Descriptions (continued)

Bit	Field	Type	Reset	Description
22	nibmode	R/W	0h	Nibble Mode 0 = Nibble mode is disabled 1 = Nibble mode is enabled
21-20	palmode	R/W	0h	Palette Loading Mode 00 = Palette and data loading, reset value 01 = Palette loading only 10 = Data loading only. Data loading only mode is allowed only 24bpp input. That is, cfg_lcdtft= 1 and cfg_tft24= 1 . The DMA is programmed to send only the video portion of the framebuffer and not the palette data prepended to a framebuffer.
19-12	reqdly	R/W	0h	Palette Loading Delay When loading the Palette from DDR, palette data is burst into the internal Palette SRAM from the Async FIFO. 1, 2, and 4 bit per pixel framebuffer encodings use a fixed 16-word entry palette residing above the video data. The 8 bit per pixel framebuffer encoding uses a 256-word entry palette residing above the video data. Likewise, 12, 16, and 24 bit per pixel framebuffer encodings also define a 256-word entry palette even though these encodings will not do a full bit-depth palette lookup. However, the 256-word palette entry must still be read from DDR as a framebuffer is fetched. Bursting in 256 words in sequential lcd_clk cycles may cause the Async FIFO to underflow depending on the SOC DDR burst bandwidth. This 8 bit reqdly parameter pauses reading of the Palette data from the Async FIFO between each burst of 16 words. The delay is in terms of lcd_clk (system clock) cycles. Value (0-255) used to specify the number of system clock cycles that should be paused between bursts of 16 word reads from the Async FIFO while loading the Palette SRAM, Programming reqdly=00h disables this pause when loading the Palette table.
11-10	Reserved			
9	nono8b	R/W	0h	Mono 8 bit 0 = lcd_pixel_o\[3:0\] is used to output four pixel values to the panel each pixel clock transition 1 = lcd_pixel_o\[7:0\] is used to output eight pixel values to the panel each pixel clock transition.This bit is ignored in all other modes
8	rdorder	R/W	0h	Raster Data Order Select (this feature was referred to as Big Endian in the OMAP LCD spec, but in reality this feature is uniquely defined for the design and is not Endianism in the classic sense) 0 = Frame buffer data used to index into the Palette lookup is ordered from least-to-most significant bit/nibble/byte/halfword. 1 = Frame buffer data used to index into the Palette lookup is ordered from most-to-least significant bit/nibble/byte/halfword
7	lcdtft	R/W	0h	LCD 0 = Passive or display operation enabled, dither logic is enabled 1 = Active or display operation enabled, external palette and DAC required, dither logic bypassed, pin timing changes to support continuous pixel clock, output enable, vsync, and hsync.
6-2	Reserved			
1	lcdbw	R/W	0h	Only Applies for Passive Matrix Panels LCD Monochrome 0 = Color operation enabled 1 = Monochrome operation enabled
0	lcden	R/W	0h	LCD Controller Enable 0 = LCD controller disabled 1 = LCD controller enabled

13.1 Introduction

Described in the following sections is the 3-port switch (3PSW) Ethernet subsystem. The 3-port switch gigabit ethernet subsystem provides ethernet packet communication and can be configured as an ethernet switch. It provides the gigabit media independent interface (GMII),reduced gigabit media independent interface (RGMII), reduced media independent interface (RMII), the management data input output (MDIO) for physical layer device (PHY) management.

13.1.1 Features

The general features of the ethernet switch subsystem are:

- Two 10/100/1000 Ethernet ports with GMII, RMII and RGMII interfaces
- Wire rate switching (802.1d)
- Non Blocking switch fabric
- Flexible logical FIFO based packet buffer structure
- Four priority level QOS support (802.1p)
- CPPI 3.1 compliant DMA controllers
- Support for Audio/Video Bridging (P802.1Qav/D6.0)
- Support for IEEE 1588 Clock Synchronization (2008 Annex D and Annex F)
  - Timing FIFO and time stamping logic inside the SS
- Device Level Ring (DLR) Support
- Address Lookup Engine
  - 1024 addresses plus VLANs
  - Wire rate lookup
  - VLAN support
  - Host controlled time-based aging
  - Spanning tree support
  - L2 address lock and L2 filtering support
  - MAC authentication (802.1x)
  - Receive or destination based Multicast and Broadcast limits
  - MAC address blocking
  - Source port locking
  - OUI host accept/deny feature
- Flow Control Support (802.3x)
- EtherStats and 802.3Stats RMON statistics gathering (shared)
- Support for external packet dropping engine
- CPGMAC_SL transmit to CPGMAC_SL receive Loopback mode (digital loopback) supported
- CPGMAC_SL receive to CPGMAC_SL transmit Loobback mode (FIFO loopback) supported
- Maximum frame size 2016 bytes (2020 with VLAN)
- 8k (2048 x 32) internal CPPI buffer descriptor memory
- MDIO module for PHY Management
- Programmable interrupt control with selected interrupt pacing
- Emulation Support.
- Programmable transmit Inter-Packet Gap (IPG)
- Reset isolation

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

13.1.2 Unsupported Features

There are 18 level interrupts from the CPGMAC module and 2 (used) level interrupts from the MDIO module. The CPSW_3GSS includes an interrupt combiner/pacer to combine these interrupts together to produce 4 interrupt outputs (per processing core). This device does not split processing among multiple cores but allows servicing of the Core0 interrupts by the Cortex A8 or the PRUSS.

The unsupported CPGMAC features in the device are shown in the following table.

Table 13-1. Unsupported CPGMAC Features

Feature	Reason
Multi-core split processing	Core 1 and Core 2 interrupts not connected.
GMII	Only 4 Rx/Tx data pins are pinned out for each port. The device supports MII (on GMII interface), RGMII, and RMII interfaces only
Phy link status	The MLINK inputs are nott pinned out. Phy link status outputs can be connected to device GPIOs.

DRAFT ONLY

13.2 Integration

This device includes a single instantiation of the three-port Gigabit Ethernet Switch Subsystem (CPSW_3GSS_RG). The switch provides 2 external ethernet ports (ports 1 and 2) and an internal CPPI interface port (port 0) with AVB/Industrial Ethernet and 802.1ae support. The subsystem consists of:

- One instance of the 3-port Gigabit switch CPSW-3G, which contains:
  - 2 CPGMAC_SL 10/100/1000 ethernet port modules with GMII interface
- Two RGMII interface modules
- Two RMII interface modules
- One MDIO interface module
- One Interrupt Controller module
- Local CPPI memory of size 8K Bytes

The integration of the Ethernet Switch is shown in Figure 13-1

Figure 13-1. Ethernet Switch Integration

13.2.1 Ethernet Switch Connectivity Attributes

The general connectivity attributes for the Ethernet Switch module are shown in Table 13-2.

Table 13-2. Ethernet Switch Connectivity Attributes

Attributes	Type
Power Domain	Peripheral Domain
Clock Domain	PD_PER_CPSW_125MHZ_GCLK (Main) PD_PER_CPSW_250MHZ_GCLK (MHZ_250_CLK) PD_PER_CPSW_50MHZ_GCLK (MHZ_50_CLK) PD_PER_CPSW_5MHZ_GCLK (MHZ_5_CLK) PD_PER_CPSW_CPTS_RFT_CLK (CPTS_RFT_CLK)
Reset Signals	CPSW_MAIN_ARST_N CPSW_ISO_MAIN_ARST_N
Idle/Wakeup Signals	Smart Idle
Interrupt Requests	4 Interrupts RX_THRESH – Receive Threshold interrupt (nonpaced) RX – Receive interrupt (paced) TX – Transmit interrupt (paced) Misc – Other interrupts All Ethernet Switch interrupts go to MPU Subsystem and PRUSS. The Subsystem contains 3 sets of interrupts C0, C1, and C2 to allow for split core processing of packets. On this device, only the C0 version of the interrupts is used.
DMA Requests	None
Physical Address	L4 Fast slave port L3 Fast initiator port

13.2.2 Ethernet Switch Clock and Reset Management

The ethernet switch controller operates in it's own clock domain and its initiator and target interfaces are connected to the L3/L4 through asynchronous bridges. The OCP interfaces are driven by the MAIN clock input. Additional reference clock inputs are provided for operating the various ethernet ports at different rates.

13.3 Functional Description

The 3 port switch (3PSW) Ethernet Subsystem peripheral are compliant to the IEEE Std 802.3 Specification. The 3PSW Ethernet Subsystem contains two RGMII/RMII interfaces,one CPPI 3.0 interface, Interrupt Controller, MDI0 and CPSW_3G which contains two GMII interfaces as shwon in the figure1 3PSW Ethernet Subsytem Top Level Block Diagram.

The Subsystem Modules are discussed in detail in the following sections.

13.3.1 CPSW_3G

The CPSW_3G GMII interfaces are compliant to the IEEE Std 802.3 Specification.

The CPSW_3G contains two CPGMAC_SL interfaces (ports 1 and 2), one CPPI 3.0 interface Host Port (port 0), Common Platform Time Sync (CPTS), ALE Engine and CPDMA.

The top level block diagram of CPSW_3G is shown below:

Figure 13-2. CPSW_3G Block Diagram

13.3.1.1 CPDMA RX and TX Interfaces

The CPDMA submodule is a CPPI 3.0 compliant packet DMA transfer controller. The CPPI 3.0 interface is port 0.

After reset, initialization, and configuration the host may initiate transmit operations. Transmit operations are initiated by host writes to the appropriate transmit channel head descriptor pointer contained in the STATERAM block. The transmit DMA controller then fetches the first packet in the packet chain from memory in accordance with CPPI 3.0 protocol. The DMA controller writes the packet into the external transmit FIFO in 64-byte bursts (maximum).

Receive operations are initiated by host writes to the appropriate receive channel head descriptor pointer after host initialization and configuration. The receive DMA controller writes the receive packet data to external memory in accordance with CPPI 3.0 protocol. See the **CPPI Buffer Descriptors** section for detailed description of Buffer Descriptors

13.3.1.1.1 Receive DMA Interface

The Receive DMA is an eight channel CPPI 3.0 compliant interface. Each channel has a single queue for frame reception.

13.3.1.1.1.1 Receive DMA Host Configuration

To configure the Rx DMA for operation the host must perform the following:

- Initialize the receive addresses.
- Initialize the **Rx_HDP** Registers to zero.
- Enable the desired receive interrupts in the **IntMask** register.
- Write the **rx_buffer_offset** register value.
- Setup the receive channel(s) buffer descriptors in host memory as required by CPPI 3.0.
- Enable the RX DMA controller by setting the **rx_en** bit in the **Rx_Control** register.

13.3.1.1.1.2 Receive Channel Teardown

The host commands a receive channel teardown by writing the channel number to the **Rx_Teardown** register. When a teardown command is issued to an enabled receive channel the following will occur:

- Any current frame in reception will complete normally.
- The **teardown_complete** bit will be set in the next buffer descriptor in the chain

if there is one.

- The channel head descriptor pointer will be cleared to zero

Copyright © 2011, Texas Instruments Incorporated

- A receive interrupt for the channel will be issued to the host.
- The host should acknowledge a teardown interrupt with a 0xfffffffc

acknowledge value

Channel teardown may be commanded on any channel at any time. The host is informed of the teardown completion by the set teardown complete buffer descriptor bit. The port does not clear any channel enables due to a teardown command. A teardown command to an inactive channel issues an interrupt that software should acknowledge with a 0xfffffffc acknowledge value (note that there is no buffer descriptor in this case). Software may read the interrupt acknowledge location to determine if the interrupt was due to a commanded teardown. The read value will be 0xfffffffc if the interrupt was due to a teardown command.

13.3.1.1.2 Transmit DMA Interface.

The Tranmsit DMA is an eight channel CPPI 3.0 compliant interface. Priority between the eight queues may be either fixed or round robin as selected by **tx_ptype** in the **DMAControl** register. If the priority type is fixed, then channel 7 has the highest priority and channel 0 has the lowest priority. Round robin priority proceeds from channel 0 to channel 7.

13.3.1.1.2.1 Transmit DMA Host Configuration

To configure the TX DMA for operation the host must do the following:

- Initialize the **Tx_HDP** registers to a zero value.
- Enable the desired transmit interrupts in the **IntMask** register.
- Setup the transmit channel(s) buffer descriptors in host memory as defined in CPPI 3.0.
- Configure and enable the transmit operation as desired in the **TxControl** register.
- Write the appropriate **Tx_HDP** registers with the appropriate values to start transmit operations.

13.3.1.1.2.2 Transmit Channel Teardown

The host commands a transmit channel teardown by writing the channel number to the **Tx_Teardown** register. When a teardown command is issued to an enabled transmit channel the following will occur:

- Any frame currently in transmission will complete normally
- The teardown complete bit will be set in the next sop buffer descriptor (if there is one).
- The channel head descriptor pointer will be set to zero.
- An interrupt will be issued to inform the host of the channel teardown.
- The host should acknowledge a teardown interrupt with a 0xfffffffc acknowledge value

Channel teardown may be commanded on any channel at any time. The host is informed of the teardown completion by the set teardown complete buffer descriptor bit. The port does not clear any channel enables due to a teardown command. A teardown command to an inactive channel issues an interrupt that software should acknowledge with a 0xfffffffc acknowledge value (note that there is no buffer descriptor in this case). Software may read the interrupt acknowledge location to determine if the interrupt was due to a commanded teardown. The read value will be 0xfffffffc if the interrupt was due to a teardown command.

13.3.1.1.3 Transmit Rate Limiting

Transmit operations can be configured to rate limit the transmit data for each transmit priority. Rate limiting is enabled for a channel when the **tx_rlim[7:0]** bit associated with that channel is set in the **DMAControl** register. Rate limited channels must be the highest priority channels. For example, if two rate limited channels are required then **tx_rlim[7:0]** should be set to 11000000 with the msb corresponding to channel 7. When any channels are configured to be rate-limiting, the priority type must be fixed for transmit. Round-robin priority type is not allowed when rate-limiting. Each of the eight transmit priorities has an

Copyright © 2011, Texas Instruments Incorporated

associated register to control the rate at which the priority is allowed to send data (**Tx_Pri(7..0)_Rate)** when the channel is rate-limiting. Each priority has a send count (**pri(7..0)_send_cnt[13:0]**) and an idle count (**pri(7..0)_idle_cnt[13:0]**). The transfer rate includes the inter-packet gap (12 bytes) and the preamble (8 bytes). The rate in Mbits/second that each priority is allowed to send is controlled by the below equation.

Priority Transfer rate in Mbit/s = ((**priN_idle_cnt**/(**priN_idle_cnt** + **priN_send_cnt**)) * frequency * 32

Where the frequency is the **CLK** frequency.

13.3.1.1.4 Command IDLE

The **cmd_idle** bit in the **DMA_Control** register allows CPDMA operation to be suspended. When the idle state is commanded, the CPDMA will stop processing receive and transmit frames at the next frame boundary. Any frame currently in reception or transmission will be completed normally without suspension. For transmission, any complete or partial frame in the tx cell fifo will be transmitted. For receive, frames that are detected by the CPDMA after the suspend state is entered are ignored. No statistics will be kept for ignored frames. Commanded idle is similar in operation to emulation control and clock stop.

13.3.1.2 Address Lookup Engine (ALE)

The address lookup engine (ALE) processes all received packets to determine which port(s) if any that the packet should the forwarded to. The ALE uses the incoming packet received port number, destination address, source address, length/type, and VLAN information to determine how the packet should be forwarded. The ALE outputs the port mask to the switch fabric that indicates the port(s) the packet should be forwarded to. The ALE is enabled when the ale_enable bit in the ALE_Control register is set. All packets are dropped when the ale_enable bit is cleared to zero.

In normal operation, the CPGMAC_SL modules are configured to issue an abort, instead of an end of packet, at the end of a packet that contains an error (runt, frag, oversize, jabber, crc, alignment, code etc.) or at the end of a mac control packet. However, when the CPGMAC_SL configuration bit(s) cef, csf, or cmf are set, error frames, short frames or mac control frames have a normal end of packet instead of an abort at the end of the packet. When the ALE receives a packet that contains errors (due to a set header error bit), or a mac control frame and does not receive an abort, the packet will be forwarded only to the host port (port 0). No ALE learning occurs on packets with errors or mac control frames. Learning is based on source address and lookup is based on destination address.

The ALE may be configured to operate in bypass mode by setting the ale_bypass bit in the ALE_Control register. When in bypass mode, all CPGMAC_SL received packets are forwarded only to the host port (port 0). Packets from the two ports can be on separate Rx DMA channels by configuring the CPDMA_Rx_Ch_Map register. In bypass mode, the ALE processes host port transmit packets the same as in normal mode. In general, packets would be directed by the host in bypass mode.

The ALE may be configured to operate in OUI deny mode by setting the enable_oui_deny bit in the ALE_Control register. When in OUI deny mode, a packet with a non-matching OUI source address will be dropped unless the destination address matches a multicast table entry with the super bit set. Broadcast packets will be dropped unless the broadcast address is entered into the table with the super bit set. Unicast packets will be dropped unless the unicast address is in the table with block and secure both set (supervisory unicast packet).

Multicast supervisory packets are designated by the super bit in the table entry. Unicast supervisory packets are indicated when block and secure are both set. Supervisory packets are not dropped due to rate limiting, OUI, or VLAN processing.

13.3.1.2.1 Address Table Entry

The ALE table contains 1024 entries. Each table entry represents a free entry, an address, a VLAN, an address/VLAN pair, or an OUI address. Software should ensure that there are not double address entries in the table. The double entry used would be indeterminate. Reserved table bits must be written with zeroes.

Copyright © 2011, Texas Instruments Incorporated

Source Address learning occurs for packets with a unicast, multicast or broadcast destination address and a unicast or multicast (including broadcast) source address. Multicast source addresses have the group bit (bit 40) cleared before ALE processing begins, changing the multicast source address to a unicast source address. A multicast address of all ones is the broadcast address which may be added to the table. A learned unicast source address is added to the table with the following control bits:

Table 13-5. Learned Address Control Bits

unicast_type	11
Block	0
Secure	0

If a received packet has a source address that is equal to the destination address then the following occurs:

- The address is learned if the address is not found in the table.
- The address is updated if the address is found.
- The packet is dropped.

Table Entry Type

00 – Free Entry

01 – Address Entry : unicast or multicast determined by dest **address bit 40 .**

10 – VLAN entry

11 – VLAN Address Entry : unicast or multicast determined by **address bit 40.**

13.3.1.2.1.1 Free Table Entry

Table 13-6. Free (Unused) Address Table Entry Bit Values

71:62	**61:60**	**59:0**

Supervisory Packet (SUPER)

When set, this field indicates that the packet with a matching multicast destination address is a supervisory packet.

0: Non-supervisory packet

1: Supervisory packet

Port Mask(2:0) (PORT_MASK)

This three bit field is the port bit mask that is returned with a found multicast destination address. There may be multiple bits set indicating that the multicast packet may be forwarded to multiple ports (but not the receiving port).

Multicast Forward State (MCAST_FWD_STATE)

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Multicast Forward State – Indicates the port state(s) required for the received port on a destination address lookup in order for the multicast packet to be forwarded to the transmit port(s). A transmit port must be in the Forwarding state in order to forward the packet. If the transmit port_mask has multiple set bits then each forward decision is independent of the other transmit port(s) forward decision.

00 – Forwarding

01 – Blocking/Forwarding/Learning

10 – Forwarding/Learning

11 – Forwarding

The forward state test returns a true value if both the Rx and Tx ports are in the required state.

Table Entry Type (ENTRY_TYPE)

Address entry type. Unicast or multicast determined by address bit 40.

01: Address entry. Unicast or multicast determined by address bit 40.

Packet Address (MULTICAST_ADDRESS)

This is the 48-bit packet MAC address. For an OUI address, only the upper 24-bits of the address are used in the source or destination address lookup. Otherwise, all 48-bits are used in the lookup.

13.3.1.2.1.3 VLAN/Multicast Address Table Entry

Table 13-8. VLAN/Multicast Address Table Entry Bit Values

71:69	68:66	65	64	63:62	61:60	59:48	47:0
Reserved	Port Mask	Super	Reserved	Mcast Fwd State	Entry Type (11)	vlan_id	Multicast Address

Supervisory Packet (SUPER)

When set, this field indicates that the packet with a matching multicast destination address is a supervisory packet.

0: Non-supervisory packet

1: Supervisory packet

Port Mask(2:0) (PORT_MASK)

This three bit field is the port bit mask that is returned with a found multicast destination address. There may be multiple bits set indicating that the multicast packet may be forwarded to multiple ports (but not the receiving port).

Multicast Forward State (MCAST_FWD_STATE)

Multicast Forward State – Indicates the port state(s) required for the received port on a destination address lookup in order for the multicast packet to be forwarded to the transmit port(s). A transmit port must be in the Forwarding state in order to forward the packet. If the transmit port_mask has multiple set bits then each forward decision is independent of the other transmit port(s) forward decision.

00 – Forwarding

01 – Blocking/Forwarding/Learning

10 – Forwarding/Learning

11 – Forwarding

The forward state test returns a true value if both the Rx and Tx ports are in the required state.

Table Entry Type (ENTRY_TYPE)

Address entry type. Unicast or multicast determined by address bit 40.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

11: VLAN address entry. Unicast or multicast determined by address bit 40.

VLAN ID (VLAN_ID)

The unique identifier for VLAN identification. This is the 12-bit VLAN ID.

Packet Address (MULTICAST_ADDRESS)

This is the 48-bit packet MAC address. For an OUI address, only the upper 24-bits of the address are used in the source or destination address lookup. Otherwise, all 48-bits are used in the lookup.

13.3.1.2.1.4 Unicast Address Table Entry

Table 13-9. Unicast Address Table Entry Bit Values

71:68	67:66	65	64	63:62	61:60	59:48	47:0
Reserved	Port Number	Block	Secure	Unicast Type (00) or (X1)	Entry Type	Reserved	Unicast Address

Port Number (PORT_NUMBER)

Port Number – This field indicates the port number (not port mask) that the packet with a unicast destination address may be forwarded to. Packets with unicast destination addresses are forwarded only to a single port (but not the receiving port).

Block (BLOCK)

Block – The block bit indicates that a packet with a matching source or destination address should be dropped (block the address).

0 – Address is not blocked.

1 – Drop a packet with a matching source or destination address (secure

must be zero)

If block and secure are both set, then they no longer mean block and secure. When both are set, the block and secure bits indicate that the packet is a unicast supervisory (super) packet and they determine the unicast forward state test criteria. If both bits are set then the packet is forwarded if the receive port is in the Forwarding/Blocking/Learning state. If both bits are not set then the packet is forwarded if the receive port is in the Forwarding state.

Secure (SECURE)

Secure – This bit indicates that a packet with a matching source address should be dropped if the received port number is not equal to the table entry port_number.

0 – Received port number is a don’t care.

1 – Drop the packet if the received port is not the secure port for the source

address and do not update the address (block must be zero)

Unicast Type (UNICAST_TYPE)

Unicast Type – This field indicates the type of unicast address the table entry contains.

00 – Unicast address that is not ageable.

01 – Ageable unicast address that has not been touched.

10 – OUI address - lower 24-bits are don’t cares (not ageable).

11 – Ageable unicast address that has been touched.

Table Entry Type (ENTRY_TYPE)

Address entry. Unicast or multicast determined by address bit 40.

01: Address entry. Unicast or multicast determined by address bit 40.

Copyright © 2011, Texas Instruments Incorporated

Packet Address (UNICAST_ADDRESS)

This is the 48-bit packet MAC address. All 48-bits are used in the lookup.

13.3.1.2.1.5 OUI Unicast Address Table Entry

Table 13-10. OUI Unicast Address Table Entry Bit Values

71:64	63:62	61:60	59:48	47:24	23:0
Reserved	Unicast Type (10)	Entry Type (01)	Reserved	Unicast OUI	Reserved

Unicast Type (UNICAST_TYPE)

Unicast Type – This field indicates the type of unicast address the table entry contains.

00 – Unicast address that is not ageable.

01 – Ageable unicast address that has not been touched.

10 – OUI address - lower 24-bits are don't cares (not ageable).

11 – Ageable unicast address that has been touched.

Table Entry Type (ENTRY_TYPE)

Address entry. Unicast or multicast determined by address bit 40.

01: Address entry. Unicast or multicast determined by address bit 40.

Packet Address (UNICAST_OUI)

For an OUI address, only the upper 24-bits of the address are used in the source or destination address lookup.

13.3.1.2.1.6 VLAN/Unicast Address Table Entry

Table 13-11. Unicast Address Table Entry Bit Values

71:68	67:66	65	64	63:62	61:60	59:48	47:0
Reserved	Port Number	Block	Secure	Unicast Type (00) or (X1)	Entry Type (11)	vlan_id	Unicast Address

Port Number (PORT_NUMBER)

Port Number – This field indicates the port number (not port mask) that the packet with a unicast destination address may be forwarded to. Packets with unicast destination addresses are forwarded only to a single port (but not the receiving port).]

Block (BLOCK)

Block – The block bit indicates that a packet with a matching source or destination address should be dropped (block the address).

0 – Address is not blocked.

1 – Drop a packet with a matching source or destination address (secure

must be zero)

If block and secure are both set, then they no longer mean block and secure. When both are set, the block and secure bits indicate that the packet is a unicast supervisory (super) packet and they determine the unicast forward state test criteria. If both bits are set then the packet is forwarded if the receive port is in the Forwarding/Blocking/Learning state. If both bits are not set then the packet is forwarded if the receive port is in the Forwarding state.

Secure (SECURE)

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Secure – This bit indicates that a packet with a matching source address should be dropped if the received port number is not equal to the table entry port_number.

0 – Received port number is a don't care.

1 – Drop the packet if the received port is not the secure port for the source

address and do not update the address (block must be zero)

Unicast Type (UNICAST_TYPE)

Unicast Type – This field indicates the type of unicast address the table entry contains.

00 – Unicast address that is not ageable.

01 – Ageable unicast address that has not been touched.

10 – OUI address - lower 24-bits are don't cares (not ageable).

11 – Ageable unicast address that has been touched.

Table Entry Type (ENTRY_TYPE)

Address entry. Unicast or multicast determined by address bit 40.

11: VLAN address entry. Unicast or multicast determined by address bit 40.

VLAN ID (VLAN_ID)

The unique identifier for VLAN identification. This is the 12-bit VLAN ID.

Packet Address (UNICAST_ADDRESS)

This is the 48-bit packet MAC address. All 48-bits are used in the lookup.

13.3.1.2.1.7 VLAN Table Entry

Table 13-12. VLAN Table Entry

71:62	61:60	59:48	47:27	26:24	23:19	18:16	15:11	10:8	7:3	2:0
Reserved	Entry Type (10)	vlan_id	Reserved	Force Untagged Egress	Reserved	Reg Mcast Flood Mask	Reserved	Unreg Mcast Flood Mask	Reserved	Vlan Member List

Table Entry Type (ENTRY_TYPE)

10: VLAN entry

VLAN ID (VLAN_ID)

The unique identifier for VLAN identification. This is the 12-bit VLAN ID.

Force Untagged Packet Egress (FORCE_UNTAGGED_EGRESS)

This field causes the packet VLAN tag to be removed on egress (except on port 0).

Registered Multicast Flood Mask (REG_MCAST_FLOOD_MASK)

Registered Multicast Flood Mask – Mask used for multicast when the multicast address is found

Unregistered Multicast Flood Mask (UNREG_MCAST_FLOOD_MASK)

Unregistered Multicast Flood Mask – Mask used for multicast when the multicast address is not found

VLAN Member List (VLAN_MEMBER_LIST)

VLAN Member List – This three bit field indicates which port(s) are members of the associated VLAN.

DRAFT ONLY

13.3.1.2.2 Packet Forwarding Processes

There are four processes that an incoming received packet may go through to determine packet forwarding. The processes are *Ingress Filtering, VLAN_Aware Lookup, VLAN_Unaware Lookup,* and *Egress*.

Packet processing begins in the *Ingress Filtering* process. Each port has an associated packet forwarding state that can be one of four values (Disabled, Blocked, Learning, or Forwarding). The default state for all ports is Disabled. The host sets the packet forwarding state for each port. The receive packet processes

In the packet ingress process (receive packet process), there is a forward state test for unicast destination addresses and a forward state test for multicast addresses. The multicast forward state test indicates the port states required for the receiving port in order for the multicast packet to be forwarded to the transmit port(s). A transmit port must be in the Forwarding state for the packet to be forwarded for transmission. The **mcast_fwd_state** indicates the required port state for the receiving port as indicated in the preceding table. The unicast forward state test indicates the port state required for the receiving port in order to forward the unicast packet. The transmit port must be in the Forwarding state in order to forward the packet. The **block** and **secure** bits determine the unicast forward state test criteria. If both bits are set then the packet is forwarded if the receive port is in the Forwarding/Blocking/Learning state. If both bits are not set then the packet is forwarded if the receive port is in the Forwarding state. The transmit port must be in the Forwarding state regardless. The forward state test used in the ingress process is determined by the destination address packet type (multicast/unicast).

In general, packets received with errors are dropped by the address lookup engine without learning, updating, or touching the address. The error condition and the abort are indicated by the CPGMAC_SL to the ALE. Packets with errors may be passed to the host (not aborted) by a CPGMAC_SL port if the port has a set **rx_cmf_en**, **rx_cef_en**, or **rx_csf_en** bit(s). Error packets that are passed to the host by the CPGMAC_SL are considered to be bypass packets by the ALE and are sent only to the host. Error packets do not learn, update, or touch addresses regardless of whether they are aborted or sent to the host. Packets with errors received by the host are forwarded as normal.

The below control bits are in the SL1/2_**MacControl** register.

rx_cef_en – This CPGMAC_SL control bit enables frames that are fragments, long, jabber, CRC, code, and alignment errors to be forwarded.

rx_csf_en – This CPGMAC_SL bit enables short frames to be forwarded.

rx_cmf_en – This CPGMAC_SL control bit enables mac control frames to be forwarded.

Please refer **TBD Document** on the configuration of Ingress *Filtering, VLAN_Aware Lookup, VLAN_Unaware Lookup,* and *Egress Process*.

13.3.1.2.3 Learning Process

The learning process is applied to each receive packet that is not aborted. The learning process is a concurrent process with the packet forwarding process.

Please refer to **TBD Document** for details on the configuration of Learnig Process

13.3.1.2.4 VLAN Aware Mode

The CPSW_3G is in VLAN aware mode when the CPSW Control register **vlan_aware** bit is set. In VLAN aware mode ports 0 receive packets (out of the CPSW_3G) may or may not be VLAN encapsulated depending on the CPSW Control register rx_vlan_encap bit. Port 0 receive packet data is never modified. VLAN is not removed regardless of the force untagged egress bit for Port 0. VLAN encapsulated receive packets have a 32-bit VLAN header encapsulation word added to the packet data.VLAN encapsulated packets are specified by a set **rx_vlan_encap** bit in the packet buffer descriptor.

Port 0 transmit packets are never VLAN encapsulated (encapsulation is not allowed).

In VLAN aware mode, transmitted packet data is changed depending on the packet type (**pkt_type**), packet priority (**pkt_pri**), and VLAN information as shown in the below tables:

Copyright © 2011, Texas Instruments Incorporated

13.3.1.2.5 VLAN Unaware Mode

The CPSW_3G is in VLAN unaware mode when the CPSW Control register **vlan_aware** bit is cleared. Port 0 receive packets (out of the CPSW_3G) may or may not be VLAN encapsulated depending on the CPSW Control register **rx_vlan_encap** bit. Port 0 transmit packets are never VLAN encapsulated.

13.3.1.3 Packet Priority Handling

Packets are received on three ports, two of which are CPGMAC_SL Ethernet ports and the third port is the CPPI host port. Received packets have a received packet priority (0 to 7 with 7 being the highest priority).

The received packet priority is the port priority for untagged packets, and the actual packet priority for priority tagged and VLAN tagged packets. The received packet priority is mapped through the receive ports associated “packet priority to header packet priority mapping register” to obtain the header packet priority (the CPDMA Rx and Tx nomenclature is reversed from the CPGMAC_SL nomenclature).

The header packet priority is mapped through the “header priority to switch priority mapping register” to obtain the hardware switch priority (0 to 3 with 3 being the highest priority). The header packet priority is then used as the actual transmit packet priority if the VLAN information is to be sent on egress.

13.3.1.4 FIFO Memory Control

Each of the three CPSW_3G ports has an identical associated FIFO. Each FIFO contains a single logical receive queue and four logical transmit queues (priority 0 through 3). Each FIFO memory contains 20,480 bytes (20k) total organized as 2560 by 64-bit words contained in a single memory instance. The FIFO memory is used for the associated port transmit and receive queues. The tx_max_blks field in the FIFO’s associated Max_Blks register determines the maximum number of 1k FIFO memory blocks to be allocated to the four logical transmit queues (transmit total). The rx_max_blks field in the FIFO’s associated Max_Blks register determines the maximum number of 1k memory blocks to be allocated to the logical receive queue. The tx_max_blks value plus the rx_max_blks value must sum to 20 (the total number of blocks in the FIFO). If the sum were less than 20 then some memory blocks would be unused.The default is 17 (decimal) transmit blocks and three receive blocks. The FIFO’s follow the naming convention of the Ethernet ports.Host Port is Port0 and External Ports are Port1,2

13.3.1.5 FIFO Transmit Queue Control

There are four transmit queues in each transmit FIFO. Software has some flexibility in determining how packets are loaded into the queues and on how packet priorities are selected for transmission (how packets are removed and transmitted from queues). All ports on the switch have identical FIFO’s. For the purposes of the below the transmit FIFO is switch egress even though the port 0 transmit FIFO is connected to the CPDMA receive (also switch egress). The CPDMA nomenclature is reversed from the CPGMAC_SL nomenclature due to legacy reasons.

13.3.1.5.1 Normal Priority Mode

When operating in normal mode, lower priority frames are dropped before higher priority frames. The intention is to give preference to higher priority frames. Priority 3 is the highest priority and is allowed to fill the FIFO. Priority 2 will drop packets if the packet is going to take space in the last 2k available. Priority 1 will drop packets if the packet is going to take space in the last 4k available. Priority 0 will drop packets if the packet is going to take space in the last 6k available. If fewer than 4 priorities are to be implemented then the priorities should be mapped such that the highest priorities are used. For example, if two priorities are going to be used then all packets should be mapped to priorities 3 and 2 and priorities 1 and 0 should be unused. Priority escalation may be used in normal priority mode if desired. Normal priority mode is configured as described below:

- Select normal priority mode by setting tx_in_sel[1:0] = 00 for all ports (default value in P0/1/2_Tx_In_Ctl)
- Configure priority mapping to use only the highest priorities if less than 4 priorities are used. Refer to the Packet Priority Handling section of this specification.

Copyright © 2011, Texas Instruments Incorporated

13.3.1.5.2 Dual Mac Mode

When operating in dual mac mode the intention is to transfer packets between ports 0 and 1 and ports 0 and 2, but not between ports 1 and 2. Each CPGMAC_SL appears as a single MAC with no bridging between MAC's. Each CPGMAC_SL has at least one unique (not the same) mac address.

Dual mac mode is configured as described below:

- Set the ale_vlan_aware bit in the ALE_Control register. This bit configures the ALE to process in vlan aware mode.The CPSW_3G vlan aware bit (vlan_aware in CPSW_Control) determines how packets VLAN's are processed on CPGMAC_SL egress and does not affect how the ALE processes packets or the packet destination. The CPSW_3G vlan aware bit may be set or not as required (must be set if VLAN's are to exit the switch).
- **Configure the Port 1 to Port 0 VLAN**

Add a VLAN Table Entry with ports 0 and 1 as members (clear the flood masks).

Add a VLAN/Unicast Address Table Entry with the Port1/0 VLAN and a port number of 0. Packets received on port 1 with this unicast address will be sent only to port 0 (egress). If multiple mac addresses are desired for this port then multiple entries of this type may be configured.

- **Configure the Port 2 to Port 0 VLAN**

Add a VLAN Table Entry with ports 0 and 2 as members (clear the flood masks).

Add a VLAN/Unicast Address Table Entry with the Port2/0 VLAN and a port number of 0. Packets received on port 2 with this unicast address will be sent only to port 0 (egress). If multiple mac addresses are desired for this port then multiple entries of this type may be configured.

- Packets from the host (port 0) to ports 1 and 2 should be directed. If directed packets are not desired then VLAN with addresses can be added for both destination ports.
- Select the dual mac mode on the port 0 FIFO by setting tx_in_sel[1:0] = 01 in P0_Tx_In_Ctl. The intention of this mode is to allow packets from both ethernet ports to be written into the FIFO without one port starving the other port.
- The priority levels may be configured such that packets received on port 1 egress on one CPDMA RX channel while packets received on port 2 egress on a different CPDMA RX channel.

13.3.1.6 Audio Video Bridging

AV Bridging is an ongoing project of IEEE 802.1 concerned with enabling low-latency streaming of time-sensitive audiovisual data over networks. Devices are designated as talkers (transmitters), bridges, or listeners (receivers). It is suggested that the maximum latency could be 2 ms over

7 hops for Class A devices and 20 ms over 7 hops for Class B devices. A hop is essentially a single local area network stage in the journey of a packet. Every time a bridge is encountered between one network section and another a hop is involved. One of the performance goals is that AVB streams will not use more than 75 percent of a link's bandwidth, leaving the remaining capacity for non-AVB streams.

The goal of developing AVB is simply--extend Ethernet's data-networking capabilities to the realm of reliable real-time audio/video networking.

An "Audio Video Bridging" network is one that implements a set of protocols being developed by the IEEE 802.1 Audio/Video Bridging Task Group. There are four primary differences between the proposed Audio Video Bridging architecture and existing 802 architectures (from now on the term "AVB" will be used instead of "Audio Video Bridging"):

- Precise synchronization - **IEEE 802.1AS:** " *Timing and Synchronization for Time-Sensitive Applications in Bridged Local Area Networks.* " a.k. a **Precision Time Protocol(PTP).**
- Traffic shaping for media streams - IEEE 802.1Qav: "*Virtual Bridged Local Area Networks:* Forwarding and Queuing for Time-Sensitive Streams."
- Admission controls - **IEEE 802.1Qat:** " *Virtual Bridged Local Area Networks - Amendment 9:* **Stream Reservation Protocol (SRP)**".
- Identification of non-participating devices - **IEEE 802.1BA:** "**Audio/Video Bridging (AVB) Systems**"

Figure 13-3. The Network static with AVB

Copyright © 2011, Texas Instruments Incorporated

The media transport protocols that work within the AVB framework are IEEE 1722: Layer 2 Transport Protocol for Time-Sensitive Streams and IEEE 1733: extends RTCP for RTP streaming over AVB-supported networks.

13.3.1.6.1 IEEE 1722: Layer 2 Transport Protocol for Time-Sensitive Streams

AVBTP or 1722 sits above the IEEE 802.1 AVB plumbing and below the application layer. It acts as the conduit between an Ethernet MAC and a streaming application.

AVBTP abstracts the underlying network transmission channel to enable the virtual connection of distributed audio and video CODECs over reliable Ethernet networks.

A complete AVBTP Ethernet packet is shown below. The below figure illustrates how IEC 61883-6 AM824 uncompressed audio samples are encapsulated in an Ethernet frame.

Figure 13-4. IEEE 1722 Packets

13.3.1.6.2 IEEE 1733: extends RTCP for RTP streaming over AVB-supported networks

This standard specifies the protocol, data encapsulations, connection management and presentation time procedures used to ensure interoperability between audio and video based end stations that use standard networking services provided by all IEEE 802 networks meeting QoS requirements for time-sensitive applications by leveraging the Real-time Transport Protocol (RTP) family of protocols and IEEE 802.1 Audio/Video Bridging (AVB) protocols.

DRAFT ONLY

13.3.1.7 Ethernet Mac Sliver (CPGMAC_SL)

The CPGMAC_SL peripheral shall be compliant to the IEEE Std 802.3 Specification. Half duplex mode is supported in 10/100 Mbps mode, but not in 1000 Mbps (gigabit) mode.

Features:

- Synchronous 10/100/1000 Mbit operation.
- G/MII Interface.
- Hardware Error handling including CRC.
- Full Duplex Gigabit operation (half duplex gigabit is not supported).
- EtherStats and 802.3Stats RMON statistics gathering support for external statistics collection module.
- Transmit CRC generation selectable on a per channel basis.
- Emulation Support.
- VLAN Aware Mode Support.
- Hardware flow control.
- Programmable Inter Packet Gap (IPG)

13.3.1.7.1 GMII/MII Media Independent Interface

The following sections cover operation of the Media Independent Interface in 10/100/1000 Mbps modes. An IEEE 802.3 compliant Ethernet MAC controls the interface.

13.3.1.7.1.1 Data Reception

13.3.1.7.1.1.1 Receive Control

Data received from the PHY is interpreted and output. Interpretation involves detection and removal of the preamble and start of frame delimiter, extraction of the address and frame length, data handling, error checking and reporting, cyclic redundancy checking (CRC), and statistics control signal generation.

13.3.1.7.1.1.2 Receive Inter-Frame Interval

The 802.3 required inter-packet gap (IPG) is 24 GMII clocks (96 bit times) for 10/100 Mbit modes, and 12 GMII clocks (96 bit times) for 1000 Mbit mode. However, the MAC can tolerate a reduced IPG (2 GMII clocks in 10/100 mode and 5 GMII clocks in 1000 mode) with a correct preamble and start frame delimiter.

This interval between frames must comprise (in the following order):

- An Inter-Packet Gap (IPG).
- A seven octet preamble (all octets 0x55).
- A one octet start frame delimiter (0x5D).

13.3.1.7.1.2 Data Transmission

The Gigabit Ethernet Mac Sliver (GMII) passes data to the PHY when enabled. Data is synchronized to the transmit clock rate. The smallest frame that can be sent is two bytes of data with four bytes of CRC (6 byte frame).

13.3.1.7.1.2.1 Transmit Control

A jam sequence is output if a collision is detected on a transmit packet. If the collision was late (after the first 64 bytes have been transmitted) the collision is ignored. If the collision is not late, the controller will back off before retrying the frame transmission. When operating in full duplex mode the carrier sense (CRS) and collision sensing modes are disabled.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

13.3.1.7.1.2.2 CRC Insertion

The MAC generates and appends a 32-bit Ethernet CRC onto the transmitted data if the transmit packet header **pass_crc** bit is zero. For the CPMAC_SL generated CRC case, a CRC at the end of the input packet data is not allowed.

If the header word **pass_crc** bit is set, then the last four bytes of the TX data are transmitted as the frame CRC. The four CRC data bytes should be the last four bytes of the frame and should be included in the packet byte count value. The MAC performs no error checking on the outgoing CRC when the **pass_crc** bit is set.

13.3.1.7.1.2.3 MTXER

The GMII_MTXER signal is not used. If an underflow condition occurs on a transmitted frame, the frame CRC will be inverted to indicate the error to the network. Underflow is a hardware error.

13.3.1.7.1.2.4 Adaptive Performance Optimization (APO)

The Ethernet MAC port incorporates Adaptive Performance Optimization (APO) logic that may be enabled by setting the **tx_pace** bit in the **MacControl** register. Transmission pacing to enhance performance is enabled when set. Adaptive performance pacing introduces delays into the normal transmission of frames, delaying transmission attempts between stations, reducing the probability of collisions occurring during heavy traffic (as indicated by frame deferrals and collisions) thereby increasing the chance of successful transmission.

When a frame is deferred, suffers a single collision, multiple collisions or excessive collisions, the pacing counter is loaded with an initial value of 31. When a frame is transmitted successfully (without experiencing a deferral, single collision, multiple collision or excessive collision) the pacing counter is decremented by one, down to zero.

With pacing enabled, a new frame is permitted to immediately (after one IPG) attempt transmission only if the pacing counter is zero. If the pacing counter is non zero, the frame is delayed by the pacing delay, a delay of approximately four inter-packet gap delays. APO only affects the IPG preceding the first attempt at transmitting a frame. It does not affect the back-off algorithm for retransmitted frames.

13.3.1.7.1.2.5 Inter-Packet-Gap Enforcement

The measurement reference for the IPG of 96 bit times is changed depending on frame traffic conditions. If a frame is successfully transmitted without collision, and **MCRS** is de-asserted within approximately 48 bit times of **MTXEN** being de-asserted, then 96 bit times is measured from **MTXEN**. If the frame suffered a collision, or if **MCRS** is not de-asserted until more than approximately 48 bit times after **MTXEN** is de-asserted, then 96 bit times (approximately, but not less) is measured from **MCRS**.

The transmit IPG can be shortened by eight bit times when enabled and triggered. The **tx_short_gap_en** bit in the **MacControl** register enables the **TX_SHORT_GAP** input to determine whether the transmit IPG is shorted by eight bit times.

13.3.1.7.1.2.6 Back Off

The Gigabit Ethernet Mac Sliver (GMII) implements the 802.3 binary exponential back-off algorithm.

13.3.1.7.1.2.7 Programmable Transmit Inter-Packet Gap

The transmit inter-packet gap (IPG) is programmable through the **Tx_Gap** register. The default value is decimal 12. The transmit IPG may be increased to the maximum value of 0x1ff. Increasing the IPG is not compatible with transmit pacing. The short gap feature will override the increased gap value, so the short gap feature may not be compatible with an increased IPG.

13.3.1.7.1.2.8 Speed, Duplex and Pause Frame Support Negotiation

The CPMAC_SL can operate in half duplex or full duplex in 10/100 Mbit modes, and can operate in full duplex only in 1000 Mbit mode. Pause frame support is included in 10/100/1000 Mbit modes as configured by the host.

13.3.1.7.1.3 GMII Interface Signal Connections and Descriptions

GMII Interface can operate in GIG/MII Modes.

In GIG(1000Mbps) Mode 3PSW operates only in Full duplex Mode.

In MII Mode(100/10 Mbps) 3PSW operates in Full duplex and Half Duplex.

The pin connections of the GMII Interace is shown in the following figure.

Figure 13-5. GMII Interface Connections

The detailed description of the signals in GIG/MII Mode are explained in the following sections.

13.3.1.7.1.3.1 GMII Interface Signal Descriptions in GIG (1000Mbps) Mode

Table 13-13. GMII Interface Signal Descriptions in GIG (1000Mbps) Mode

Signal	Type	Description
GMTCLK	O	The transmit clock is a continuous clock that provides the timing reference for transmit operations. The clock is generated by the CPSW and is 125 MHz at 1000 Mbps operation.
MtCLK	I	The transmit clock is a continuous free running clock and is generated by the PHY.
Mtxd	O	The transmit data pins are a collection of 8 data signals comprising 8 bits of data. MTXD0 is the least-significant bit (LSB). The signals are synchronized by GMTCLK and valid only when MTXEN is asserted.
Mtxen	O	The transmit enable signal indicates that the MTXD pins are generating 8bit data for use by the PHY. It is driven synchronously by GMTCLK.
MCOL	I	In full-duplex operation, the MCOL pin is used for hardware transmit flow control. Asserting the MCOL pin will stop packet transmissions; packets in the process of being transmitted when MCOL is asserted will complete transmission. The MCOL pin should be held low if hardware transmit flow control is not used.
MCRS	I	In full-duplex operation, the MCRS pin should be held low.
MRCLK	I	The receive clock is a continuous clock that provides the timing reference for receive operations. The MRXD,MRXDV, and MRXER signals are tied to this clock.The clock is generated by the PHY and is 125 MHz at 1000Mbps of operation.
MRXD	I	The receive data pins are a collection of 8 data signals comprising 8 bits of data.MRXD0 is the least-significant bit (LSB).The signals are synchronized by MRCLK and valid only when MRXDV is asserted.
MRXDV	I	The receive data valid signal indicates that the MRXD pins are generating byte data for use by the 3PSW. It is driven synchronously to MRCLK.
MDCLK	O	Management data clock (MDIO_CLK). The MDIO data clock is sourced by the MDIO module on the system. It is used to synchronize MDIO data access operations done on the MDIO pin.
MDIO	I/O	MDIO DATA(MDI0_D). MDIO data pin drives PHY management data into and out of the PHY by way of an access frame consisting of start of frame, read/write indication,PHY address, register address, and data bit cycles. The MDIO_D pin acts as an output for all but the data bit cycles at which time it is an input for read operations.

13.3.1.7.1.3.2

Table 13-14. GMII Interface Signal Descriptions in MII (100/10Mbps) Mode

Signal	Type	Description
GMTCLK	O	The clock is generated by the CPSW and is running at 125 MHz
MtCLK	I	The transmit clock is a continuous clock that provides the timing reference for transmit operations. The MTXD and MTXEN signals are tied to this clock. The clock is generated by the PHY and is 2.5 MHz at 10 Mbps operation and 25 MHz at 100 Mbps operation.

Table 13-14. GMII Interface Signal Descriptions in MII (100/10Mbps) Mode (continued)

Signal	Type	Description
Mtxd	O	MTXD[7-4] pins of MTXD data are not used.The transmit data pins are a collection of 4 data signals MTXD[3-0] comprising 4 bits of data. MTXD0 is the least-significant bit (LSB). The signals are synchronized by MTCLK and valid only when MTXEN is asserted.
Mtxen	O	The transmit enable signal indicates that the MTXD pins are generating 4bit data for use by the PHY. It is driven synchronously by MTCLK.
MCOL	I	In half-duplex operation, the MCOL pin is asserted by the PHY when it detects a collision on the network. It remains asserted while the collision condition persists.This signal is not necessarily synchronous to MTCLK nor MRCLK. In full-duplex operation, the MCOL pin is used for hardware transmit flow control. Asserting the MCOL pin will stop packet transmissions; packets in the process of being transmitted when MCOL is asserted will complete transmission. The MCOL pin should be held low if hardware transmit flow control is not used
MCRS	I	In half-duplex operation, the MCRS pin is asserted by the PHY when the network is not idle in either transmit or receive. The pin is deasserted when both transmit and receive are idle. This signal is not necessarily synchronous to MTCLK nor MRCLK. In full-duplex operation, the MCRS pin should be held low.
MRCLK	I	The receive clock is a continuous clock that provides the timing reference for receive operations. The MRXD, MRXDV, and MRXER signals are tied to this clock. The clock is generated by the PHY and is 2.5 MHz at 10 Mbps operation and 25 MHz at 100 Mbps operation.
MRXD	I	MRXD[7-4] bits are unused in the MII mode**.**The receive data pins are a collection of 4 data signals comprising 4 bits of data.MRXD0 is the least-significant bit (LSB).The signals are synchronized by MRCLK and valid only when MRXDV is asserted.
MRXDV	I	The receive data valid signal indicates that the MRXD pins are generating nibble data for use by the 3PSW. It is driven synchronously to MRCLK.
MDCLK	O	Management data clock (MDIO_CLK). The MDIO data clock is sourced by the MDIO module on the system. It is used to synchronize MDIO data access operations done on the MDIO pin.
MDIO	I/O	MDIO DATA(MDI0_D). MDIO data pin drives PHY management data into and out of the PHY by way of an access frame consisting of start of frame, read/write indication,PHY address, register address, and data bit cycles. The MDIO_D pin acts as an output for all but the data bit cycles at which time it is an input for read operations.

13.3.1.7.2 RMII Interface

The CPRMII peripheral shall be compliant to the RMII specification document.

Features:

- Source Synchronous 10/100 Mbit operation.
- Full and Half Duplex support.

13.3.1.7.2.1 RMII Receive (RX)

The CPRMII receive (RX) interface converts the input data from the external RMII PHY (or switch) into the required MII (CPGMAC) signals. The carrier sense and collision signals are determined from the RMII input data stream and transmit inputs as defined in the RMII specification.

An asserted **RMRXER** on any di-bit in the received packet will cause an **MRXER** assertion to the CPGMAC during the packet. In 10Mbps mode, the error is not required to be duplicated on 10 successive clocks. Any di-bit which has an asserted RMII_RXER during any of the 10 replications of the data will cause the error to be propagated.

Any received packet that ends with an improper nibble boundary aligned **RMCRSDV** toggle will issue an **MRXER** during the packet to the CPGMAC. Also, a change in speed or duplex mode during packet operations will cause packet corruption.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

The CPRMII can accept receive packets with shortened preambles, but 0x55 followed by a 0x5d is the shortest preamble that will be recognized (1 preamble byte with the start of frame byte). At least one byte of preamble with the start of frame indicator is required to begin a packet. An asserted **RMCRSDV** without at least a single correct preamble byte followed by the start of frame indicator will be ignored.

13.3.1.7.2.2 RMII Transmit (TX)

The CPRMII transmit (TX) interface converts the 3PSW MII input data into the RMII transmit format. The data is then output to the external RMII PHY.

The 3PSW does not source the transmit error (MII TXERR) signal. Any transmit frame from the CPGMAC with an error (ie. underrun) will be indicated as an error by an error CRC. Transmit error is assumed to be deasserted at all times and is not an input into the CPRMII module.Zeroes are output on RMTXD[1:0] for each clock that RMTXEN is deasserted.

13.3.1.7.2.3 RMII Signal Connections and Descriptions

The following figure shows a device with integrated 3PSW and MDIO interfaced via a RMII connection in a typical system.

The individual CPSW and MDIO signals for the RMII interface are summarized in the following figure.

For more information, see either the IEEE 802.3 standard or ISO/IEC 8802-3:2000(E).

Figure 13-6. RMII Interface Connections

Table 13-15.

Signal	Type	Description
RMTXD [1-0]	O	Transmit data (RMII_TXD). The transmit data pins are a collection of 2 bits of data. RMTDX0 is the least-significant bit (LSB). The signals are synchronized by RMREFCLK and valid only when RMTXEN is asserted.
RMXEN	O	Transmit enable (RMII_TXEN). The transmit enable signal indicates that the RMII_TXD pins are generating data for use by the PHY. RMII_TXEN is synchronous to RMII_MHZ_50_CLK.
RMREFCLK	I/O	RMII reference clock. (RMII_MHZ_50_CLK) The reference clock is used to synchronize all RMII signals. RMREFCLK must be continuous and fixed at 50 MHz.
RMRXD [1-0]	I	Receive data (RMII_RXD). The receive data pins are a collection of 2 bits of data. RMRDX0 is the least-significant bit (LSB). The signals are synchronized by RMREFCLK and valid only when RMCRSDV is asserted and RMRXER is deasserted.
RMCRSDV	I	Carrier sense/receive data valid (RMCRSDV). Multiplexed signal between carrier sense and receive data valid.
RMRXER	I	Receive error (RMII_RXER). The receive error signal is asserted to indicate that an error was detected in the received frame.
MDCLK	O	Management data clock (MDIO_CLK). The MDIO data clock is sourced by the MDIO module on the system. It is used to synchronize MDIO data access operations done on the MDIO pin.
MDIO	I/O	MDIO DATA(MDI0_D). MDIO data pin drives PHY management data into and out of the PHY by way of an access frame consisting of start of frame, read/write indication,PHY address, register address, and data bit cycles. The MDIO_D pin acts as an output for all but the data bit cycles at which time it is an input for read operations.

13.3.1.7.3 RGMII Interface

The CPRGMII peripheral shall be compliant to the RGMII specification document.

Features:

- Supports 1000/100/10 Mbps Speed.
- MII mode is not supported.

Copyright © 2011, Texas Instruments Incorporated

- Selectable internal delay on transmit.

13.3.1.7.3.1 RGMII Receive (RX)

The CPRGMII receive (RX) interface converts the source synchronous DDR input data from the external RGMII PHY into the required G/MII (CPGMAC) signals.

13.3.1.7.3.2 In-Band Mode of Operation

The CPRGMII is operating in the in-band mode of operation when the **RGMII_RX_INBAND** input is asserted.RGMII_RX_INPUT is asserted by configuring the ext_en bit to 1 of sl_mac_control register.The link status, duplexity, and speed are determined from the RGMII input data stream as defined in the RGMII specification. The link speed is indicated as shown in the following table:

RGMII_SPEED(1:0)	Link Speed
00	10 Mbs mode
01	100 Mbs mode
10	1000 Mbs mode
11	reserved

13.3.1.7.3.3 Forced Mode of Operation

The CPRGMII is operating in the forced mode of operation when the **RGMII_RX_INBAND** input is deasserted. In the forced mode of operation, the in-band data is ignored if present. The link status is forced high, and the duplexity and speed are determined from the **RGMII_FULLDUPLEX_IN** and **RGMII_GIG_IN** inputs. If the **RGMII_GIG_IN** input is asserted, then operation is gigabit mode (**RGMII_SPEED (1:0)** = 10). If the **RGMII_GIG_IN** input is deasserted, the operation is 100mbps mode (**RGMII_SPEED (1:0)** = 01).

13.3.1.7.3.4 RGMII Transmit (TX)

The CPRGMII transmit (TX) interface converts the CPGMAC G/MII input data into the DDR RGMII format. The DDR data is then output to the external PHY.

The CPGMAC does not source the transmit error (MTXERR) signal. Any transmit frame from the CPGMAC with an error (ie. underrun) will be indicated as an error by an error CRC. Transmit error is assumed to be deasserted at all times and is not an input into the CPRGMII module.

In 10/100 mode, the MTXD (7:0) data bus uses only the lower nibble. The CPRGMII will output the lower nibble twice in 10/100 mode to avoid unnecessary signal switching.

Packets will be precluded from transmission through the CPRGMII module for 4096 transmit clocks after the rising edge of **RGMII_LINK**. Packet transmission will begin on the first **GMII_MTXEN** rising edge after the 4096 transmit clock count has expired.

The RGMII0/1_ID_MODE bit value in the GMII_SEL register determines whether or not the transmit delay is included in the CPRGMII or not. When RGMII0/1_ID_MODE bit is zero, the transmit delay is included. The RGMII0/1_ID_MODE input is a configuration input only and is not intended to be changed during packet operations.

Please refer to the **Device Control Module** Document, **MII mode selection register (GMII_SEL)** to configure the CPRGMII Internal Delay/No Delay in Transmit Mode of Operation.

13.3.1.7.3.5 RGMII Signal Connections and Descriptions

The below figure shows a device with integrated CPSW and MDIO interfaced via a RGMII connection in a typical system.

The individual CPSW and MDIO signals for the RGMII interface are summarized in Figur6.

Figure 13-7. RGMII Interface Connections

Table 13-16.

Signal	Type	Description
RGTXD [3-0]	O	The transmit data pins are a collection of 4 bits of data.RGTDX0 is the least-significant bit (LSB). The signals are valid only when RGTXCTL is asserted.
RGTXCTL	O	Transmit Control/enable .The transmit enable signal indicates that the RGTXD pins are generating data for use by the PHY.
RGTXC	O	The transmit reference clock will be 125Mhz, 25Mhz, or 2.5Mhz depending on speed of operation.
RGRXD [3-0]	I	The receive data pins are a collection of 4 bits of data. RGRDX0 is the least-significant bit (LSB). The signals are valid only when RGRXCTL is asserted.
RGRXCTL	I	The receive data valid/control signal indicates that the RGRXD pins are nibble data for use by the 3PSW.
RGRXC	I	The receive clock is a continuous clock that provides the timing reference for receive operations.The clock is generated by the PHY and is 2.5 MHz at 10 Mbps operation and 25 MHz at 100 Mbps operation,125 MHz at 1000Mbps of operation.
MDCLK	O	Management data clock (MDIO_CLK). The MDIO data clock is sourced by the MDIO module on the system. It is used to synchronize MDIO data access operations done on the MDIO pin.
MDIO	I/O	MDIO DATA(MDI0_D). MDIO data pin drives PHY management data into and out of the PHY by way of an access frame consisting of start of frame, read/write indication,PHY address, register address, and data bit cycles. The MDIO_D pin acts as an output for all but the data bit cycles at which time it is an input for read operations.

13.3.1.7.4 Frame Classification

Received frames are proper (good) frames if they are between 64 and **rx_maxlen** in length (inclusive) and contain no errors (code/align/CRC).

Received frames are long frames if their frame count exceeds the value in the **rx_maxlen** register. The **rx_maxlen** register reset (default) value is 1518 (dec). Long received frames are either oversized or jabber frames. Long frames with no errors are oversized frames. Long frames with CRC, code, or alignment errors are jabber frames.

Received frames are short frames if their frame count is less than 64 bytes. Short frames that contain no errors are undersized frames. Short frames with CRC, code, or alignment errors are fragment frames.

A received long packet will always contain **rx_maxlen** number of bytes transferred to memory (if **rx_cef_en** = 1). An example with **rx_maxlen** = 1518 is below:

- If the frame length is 1518, then the packet is not a long packet and there will be 1518 bytes transferred to memory.
- If the frame length is 1519, there will be 1518 bytes transferred to memory. The last three bytes will be the first three CRC bytes.
- If the frame length is 1520, there will be 1518 bytes transferred to memory. The last two bytes will be the first two CRC bytes.
- If the frame length is 1521, there will be 1518 bytes transferred to memory. The last byte will be the first CRC byte.

If the frame length is 1522, there will be 1518 bytes transferred to memory. The last byte will be the last data byte.

13.3.1.8 Embedded Memories

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Memory Type Description	Number of Instances
Two port 36-word by 32-bit RAM	1 (STATISTICS)
Single port 2560 by 64 RAM	3 (Packet FIFOs)
Single port 64-word by 1152-bit RAM	1 (ALE)
Single port 2048-word by 32-bit RAM	1 (CPPI)

13.3.1.9 Flow Control

There are two types of switch flow control – CPPI port flow control and Ethernet port flow control. The CPPI and Ethernet port naming conventions for data flow into and out of the switch are reversed. For the CPPI port (port 0), transmit operations move packets from external memory into the switch and then out to either or both Ethernet transmit ports (ports 1 and 2). CPPI receive operations move packets that were received on either or both Ethernet receive ports to external memory.

13.3.1.9.1 CPPI Port Flow Control

The CPPI port has flow control available for transmit (switch ingress). CPPI receive operations (switch egress) do not require flow control. CPPI Transmit flow control is initiated when enabled and triggered. CPPI transmit flow control is enabled by setting the p0_flow_en bit in the **CPSW_Flow_Control** register. CPPI transmit flow control is enabled by default on reset because host packets should not be dropped in any mode of operation.

13.3.1.9.2 Ethernet Port Flow Control

The Ethernet ports have flow control available for transmit and receive. Transmit flow control stops the Ethernet port from transmitting packets to the wire (switch egress) in response to a received pause frame. Transmit flow control does not depend on FIFO usage.

The ethernet ports have flow control available for receive operations (packet ingress). Ethernet port receive flow control is initiated when enabled and triggered. Packets received on an ethernet port can be sent to the other ethernet port or the CPPI port (or both). Each destination port can trigger the receive ethernet port flow control. An ethernet destination port triggers another ethernet receive flow control when the destination port is full.

When a packet is received on an ethernet port interface with enabled flow control the below occurs:

- The packet will be sent to all ports that currently have room to take the entire packet.
- The packet will be retried until successful to all ports that indicate they don't have room for the packet.

The flow control trigger to the CPGMAC_SL will be asserted until the packet has been sent, and there is room in the logical receive FIFO for packet runout from another flow control trigger (**rx_pkt_cnt** = 0). Ethernet port receive flow control is disabled by default on reset. Ethernet port receive flow control requires that the **rx_flow_en** bit in the associated CPGMAC_SL be set to one. When receive flow control is enabled on a port, the port's associated FIFO block allocation must be adjusted. The port RX allocation must increase from the default three blocks to accommodate the flow control runout. A corresponding decrease in the TX block allocation is required. If a sending port ignores a pause frame then packets may overrun on receive (and be dropped) but will not be dropped on transmit. If flow control is disabled for gmii ports, then any packets that are dropped are dropped on transmit and not on receive.

13.3.1.9.2.1 Receive Flow Control

When enabled and triggered, receive flow control is initiated to limit the CPGMAC_SL from further frame reception. Half-duplex mode receive flow control is collision based while full duplex mode issues 802.3X pause frames. In either case, receive flow control prevents frame reception by issuing the flow control appropriate for the current mode of operation. Receive flow control is enabled by the **rx_flow_en** bit in the **MacControl** register. Receive flow control is triggered (when enabled) when the **RX_FLOW_TRIGGER** input is asserted. The CPGMAC_SL is configured for collision or IEEE 802.3X flow control via the **fullduplex** bit in the **MacControl** register.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

13.3.1.9.2.1.1 Collision Based Receive Buffer Flow Control

Collision-based receive buffer flow control provides a means of preventing frame reception when the port is operating in half-duplex mode (**fullduplex** is cleared in **MacControl)**. When receive flow control is enabled and triggered, the port will generate collisions for received frames. The jam sequence transmitted will be the twelve byte sequence C3.C3.C3.C3.C3.C3.C3.C3.C3.C3.C3.C3 (hex). The jam sequence will begin no later than approximately as the source address starts to be received. Note that these forced collisions will not be limited to a maximum of 16 consecutive collisions, and are independent of the normal back-off algorithm. Receive flow control does not depend on the value of the incoming frame destination address. A collision will be generated for any incoming packet, regardless of the destination address.

13.3.1.9.2.1.2 IEEE 802.3X Based Receive Flow Control

IEEE 802.3x based receive flow control provides a means of preventing frame reception when the port is operating in full-duplex mode (**fullduplex** is set in **MacControl)**. When receive flow control is enabled and triggered, the port will transmit a pause frame to request that the sending station stop transmitting for the period indicated within the transmitted pause frame.

The CPGMAC_SL will transmit a pause frame to the reserved multicast address at the first available opportunity (immediately if currently idle, or following the completion of the frame currently being transmitted). The pause frame will contain the maximum possible value for the pause time (0xFFFF). The MAC will count the receive pause frame time (decrements 0xFF00 downto zero) and retransmit an outgoing pause frame if the count reaches zero. When the flow control request is removed, the MAC will transmit a pause frame with a zero pause time to cancel the pause request.

Note that transmitted pause frames are only a request to the other end station to stop transmitting. Frames that are received during the pause interval will be received normally (provided the Rx FIFO is not full).

Pause frames will be transmitted if enabled and triggered regardless of whether or not the port is observing the pause time period from an incoming pause frame.

The CPGMAC_SL will transmit pause frames as described below:

- The 48-bit reserved multicast destination address 01.80.C2.00.00.01.
- The 48-bit source address –**SL_SA(47:0)**.
- The 16-bit length/type field containing the value 88.08
- The 16-bit pause opcode equal to 00.01
- The 16-bit pause time value FF.FF. A pause-quantum is 512 bit-times. Pause frames sent to cancel a pause request will have a pause time value of 00.00.
- Zero padding to 64-byte data length (The CPGMAC_SL will transmit only 64 byte pause frames).
- The 32-bit frame-check sequence (CRC word).

All quantities above are hexadecimal and are transmitted most-significant byte first. The least-significant bit is transferred first in each byte.

If **rx_flow_en** is cleared to zero while the pause time is nonzero, then the pause time will be cleared to zero and a zero count pause frame will be sent.

13.3.1.9.2.2 Transmit Flow Control

Incoming pause frames are acted upon, when enabled, to prevent the CPGMAC_SL from transmitting any further frames. Incoming pause frames are only acted upon when the **fullduplex** and **tx_flow_en** bits in the **MacControl** register are set. Pause frames are not acted upon in half-duplex mode. Pause frame action will be taken if enabled, but normally the frame will be filtered and not transferred to memory. MAC control frames will be transferred to memory if the **rx_cmf_en** (Copy MAC Frames) bit in the **MacControl** register is set. The **tx_flow_en** and **fullduplex** bits effect whether or not MAC control frames are acted upon, but they have no effect upon whether or not MAC control frames are transferred to memory or filtered.

Pause frames are a subset of MAC Control Frames with an opcode field=0x0001. Incoming pause frames will only be acted upon by the port if:

Copyright © 2011, Texas Instruments Incorporated

- **tx_flow_en** is set in **MacControl**, and
- the frame's length is 64 to **rx_maxlen** bytes inclusive, and
- the frame contains no crc error or align/code errors.

The pause time value from valid frames will be extracted from the two bytes following the opcode. The pause time will be loaded into the port's transmit pause timer and the transmit pause time period will begin.

If a valid pause frame is received during the transmit pause time period of a previous transmit pause frame then:

- if the destination address is not equal to the reserved multicast address or any enabled or disabled unicast address, then the transmit pause timer will immediately expire, or
- if the new pause time value is zero then the transmit pause timer will immediately expire, else
- the port transmit pause timer will immediately be set to the new pause frame pause time value. (Any remaining pause time from the previous pause frame will be discarded).

If **tx_flow_en** in **MacControl** is cleared, then the pause-timer will immediately expire.

The port will not start the transmission of a new data frame any sooner than 512-bit times after a pause frame with a non-zero pause time has finished being received (**MRXDV** going inactive). No transmission will begin until the pause timer has expired (the port may transmit pause frames in order to initiate outgoing flow control). Any frame already in transmission when a pause frame is received will be completed and unaffected.

Incoming pause frames consist of the below:

- A 48-bit destination address equal to:
- The reserved multicast destination address 01.80.C2.00.00.01, or
- The SL_SA(47:0) input mac source address.
- The 48-bit source address of the transmitting device.
- The 16-bit length/type field containing the value 88.08
- The 16-bit pause opcode equal to 00.01
- The 16-bit pause_time. A pause-quantum is 512 bit-times.
- Padding to 64-byte data length.
- The 32-bit frame-check sequence (CRC word).

All quantities above are hexadecimal and are transmitted most-significant byte first. The least-significant bit is transferred first in each byte.

The padding is required to make up the frame to a minimum of 64 bytes. The standard allows pause frames longer than 64 bytes to be discarded or interpreted as valid pause frames. The CPGMAC_SL will recognize any pause frame between 64 bytes and **rx_maxlen** bytes in length.

13.3.1.10 Short Gap

The port 1 (and port 2) transmit inter-packet gap (IPG) may be shortened by eight bit times when enabled and triggered. The **tx_short_gap_en** bit in the **SL1_MacControl (SL2_MacControl)** register enables the gap to be shortened when triggered. The condition is triggered when the port 1 (port 2) transmit FIFO has a user defined number of FIFO blocks used. The port 1 transmit FIFO blocks used determines if the port 1 gap is shortened, and the port 2 transmit FIFO blocks used determines if the port 2 gap is shortened. The **CPSW_Gap_Thresh** register value determines the port 1 short gap threshold, and the **CPSW_Gap_Thresh** register value determines the port 2 short gap threshold.

13.3.1.11 Switch Latency

The CPSW_3G is a store and forward switch. The switch latency is defined as the amount of time between the end of packet reception of the received packet to the start of the output packet transmit.

DRAFT ONLY

Mode	Latency
Gig (1000)	880ns
100	1.3us
10	6.5us

13.3.1.12 Emulation Control

The emulation control input (EMUSUSP) and submodule emulation control registers allow CPSW_3G operation to be completely or partially suspended. There are three CPSW_3G submodules that contain emulation control registers (CPGMAC_SL1, CPGMAC_SL2, and CPDMA). The submodule emulation control registers must be accessed to facilitate CPSW_3G emulation control. The CPSW_3G module enters the emulation suspend state if all three submodules are configured for emulation suspend and the emulation suspend input is asserted. A partial emulation suspend state is entered if one or two submodules is configured for emulation suspend and the emulation suspend input is asserted. Emulation suspend occurs at packet boundaries. The emulation control feature is implemented for compatibility with other peripherals.

CPGMAC_SL Emulation Control

The emulation control input (**TBEMUSUP**) and register bits (**soft** and **free** in the **EMControl** register) allow CPGMAC_SL operation to be suspended. When the emulation suspend state is entered, the CPGMAC_SL will stop processing receive and transmit frames at the next frame boundary. Any frame currently in reception or transmission will be completed normally without suspension. For receive, frames that are detected by the CPGMAC_SL after the suspend state is entered are ignored. Emulation control is implemented for compatibility with other peripherals.

CPDMA Emulation Control

The emulation control input (**TBEMUSUP**) and register bits (**soft** and **free** in the **EMControl** register) allow CPDMA operation to be suspended. When the emulation suspend state is entered, the CPDMA will stop processing receive and transmit frames at the next frame boundary. Any frame currently in reception or transmission will be completed normally without suspension. For transmission, any complete or partial frame in the tx cell fifo will be transmitted. For receive, frames that are detected by the CPDMA after the suspend state is entered are ignored. No statistics will be kept for ignored frames. Emulation control is implemented for compatibility with other peripherals

The following table shows the operations of the emulation control input and register bits:

Table 13-17. Operations of Emulation Control Input and Register Bits

EMUSUSP	soft	free	Description
0	X	X	Normal Operation
1	0	0	Normal Operation
1	1	0	Emulation Suspend
1	X	1	Normal Operation

13.3.1.13 Software IDLE

The submodule software idle register bits enable CPSW_3G operation to be completely or partially suspended by software control. There are three CPSW_3G submodules that contain software idle register bits (CPGMAC_SL1, CPGMAC_SL2, and CPDMA). Each of the three submodules may be individually commanded to enter the idle state. The idle state is entered at packet boundaries, and no further packet operations will occur on an idled submodule until the idle command is removed. The CPSW_3G module enters the idle state when all three submodules are commanded to enter and have entered the idle state. Idle status is determined by reading or polling the three submodule idle bits. The CPSW_3G is in the idle state when all three submodules are in the idle state. The **CPSW_Soft_Idle** bit may be set if desired after the submodules are in the idle state. The **CPSW_Soft_Idle** bit causes packets to not be transferred from one FIFO to another FIFO internal to the switch.

Copyright © 2011, Texas Instruments Incorporated

13.3.1.14 Software Reset

The CPSW_3G software reset register, CPSW_3GSS software reset register and the three submodule software reset registers enable the CPSW_3GSS to be reset by software. There are three CPSW_3G submodules that contain software reset registers (CPGMAC_SL1, CPGMAC_SL2, and CPDMA). Each of the three submodules may be individually commanded to be reset by software.

For the CPDMA, the reset state is entered at packet boundaries, at which time the CPDMA reset occurs. The CPGMAC_SL soft reset is immediate. Submodule reset status is determined by reading or polling the submodule reset bit. If the submodule reset bit is read as a one, then the reset process has not yet completed. The submodule soft reset process could take up to 2ms each. The reset has completed if the submodule reset bit is read as a zero.

After all three submodules (in any order) have been reset and a read of each submodule reset bit indicates that the reset process is complete, the CPSW_3G software reset register bit may be written to complete the CPSW_3G module software reset operation. The CPSW_3G software reset bit controls the reset of the FIFO's, the statistics submodule, and the address lookup engine (ALE). The CPSW_3G software reset is immediate and will be indicated by reading a zero from the soft reset bit.

The CPSW_3GSS software reset bit controls the reset of the INT, REGS and CPPI. The CPSW_3GSS software reset is immediate and will be indicated by reading a zero from the soft reset bit.

13.3.1.15 FIFO Loopback

FIFO loopback mode is entered when the **fifo_loopback** bit in the **CPSW_Control** register is set. FIFO loopback mode causes packets received on a port to be turned around and transmitted back on the same port. Port 0 receive is fixed on channel zero in FIFO loopback mode. The **RXSOFOVERRUN** statistic is incremented for each packet sent in FIFO loopback mode. Packets sent in with errors are returned with errors (they are not dropped). FIFO loopback is intended as a simple mechanism for test purposes. FIFO loopback should be performed in fullduplex mode only.

13.3.2 Common Platform Time Sync

The Common Platform Time Sync (CPTS) module is used to facilitate host control of time sync operations. It enables compliance with the IEEE 1588-2008 standard for a precision clock synchronization protocol.

13.3.2.1 Architecture

Figure 13-8. CPTS Block Diagram

Figure 1 shows the architecture of the CPTS module inside the 3PSW Ethernet Subsystem. Time stamp values for every packet transmitted or received on either port of the 3PSW are recorded. At the same time, each packet is decoded to determine if it is a valid time sync event. If so, an event is loaded into the Event FIFO for processing containing the recorded time stamp value when the packet was transmitted or received.

In addition, both hardware (**HWx_TS_PUSH**) and software (**TS_PUSH**) can be used to read the current time stamp value though the Event FIFO

The reference clock used for the time stamp (**RCLK**) is sourced from one of the five sources, as shown in Figure 2. The PLL used for sourcing **RCLK** can be selected by configuring the **RMII _REFCLK_SRC** register in the Device Control Module. Please refer to the Device Control Module document for more details. Note that if RGMII mode is used, RCLK must be exactly 250 MHz.

Figure 13-9. CPTS RCLK Source

13.3.2.2 Common Platform Time Sync Initialization

The CPTS module should be configured using the following steps:

- Reset the CPTS module
- Clear the CPTS_EN bit in the CONTROL register
- Write the CPTS_RFT_CLK value in the RMII_RFTCLK_SEL register with the desired reference clock selection
- Set the CPTS_EN bit in the CONTROL register
- If using interrupts and not polling, enable the interrupt by setting the TS_PEND_EN bit in the TS_INT_ENABLE register.

13.3.2.3 Time Stamp Value

The time stamp value is a 32-bit value that increments on each RCLK rising edge when CPTS_EN is set to one. When CPTS_EN is cleared to zero the time stamp value is reset to zero. If more than 32-bits of time stamp are required by the application, the host software must maintain the necessary number of upper bits. The upper time stamp value should be incremented by the host when the rollover event is detected.

For test purposes, the time stamp can be written via the time stamp load function (TS_LOAD_VAL and TS_LOAD_EN registers).

13.3.2.4 Event FIFO

All time sync events are push onto the Event FIFO. There are 16 locations in the event FIFO with no overrun indication supported. Software must service the event FIFO in a timely manner to prevent FIFO overrun.

13.3.2.5 Time Sync Events

Time Sync events are 64-bit values that are pushed onto the event FIFO and read in two 32-bit reads. The definition for the two 32-bit registers, EVENT_HIGH and EVENT_LOW, is shown in the Register section of this document.

There are five types of sync events

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

- Time stamp push event
- Time stamp counter rollover event
- Time stamp counter half-rollover event
- Ethernet receive event
- Ethernet transmit event

13.3.2.5.1 Time Stamp Push Event

Software can obtain the current time stamp value (at the time of the write) by initiating a time stamp push event. The push event is initiated by setting the TS_PUSH bit of the TS_PUSH register. The time stamp value is returned in the event, along with a time stamp push event code. Software should not push a second time stamp event on to the FIFO until the first time stamp value has been read from the event FIFO.

13.3.2.5.2 Time Stamp Counter Rollover Event

The CPTS module contains a 32-bit time stamp value. The counter upper bits are maintained by host software. The rollover event indicates to software that the time stamp counter has rolled over from 0xFFFF_FFFF to 0x0000_0000, and the software maintained upper count value should be incremented.

13.3.2.5.3 Time Stamp Counter Half-rollover Event

The CPTS includes a time stamp counter half-rollover event. The half-rollover event indicates to software that the time stamp value has incremented from 0x7FFF_FFFF to 0x8000_0000. The half-rollover event is included to enable software to correct a misaligned event condition.The half-rollover event is included to enable software to determine the correct time for each event that contains a valid time stamp value – such as an Ethernet event. If an Ethernet event occurs around a counter rollover (full rollover), the rollover event could possibly be loaded into the event FIFO before the Ethernet event, even though the Ethernet event time was actually taken before the rollover. Figure 3 below shows a misalignment condition.

Figure 13-10. Event FIFO Misalignment Condition

Host software must detect and correct for misaligned event conditions. For every event after a rollover and before a half-rollover, software must examine the time stamp most significant bit. If bit 31 of the time stamp value is low (0x0000_0000 through 0x7FFF_FFFF), then the event time stamp was taken after the rollover and no correction is required. If the value is high (0x8000_0000 through 0xFFFF_FFFF), the time stamp value was taken before the rollover and a misalignment is detected. The misaligned case indicates to software that it must subtract one from the upper count value stored in software to calculate the correct time for the misaligned event.The misaligned event occurs only on the rollover boundary and not on the half-rollover boundary. Software only needs to check for misalignment from a rollover event to a half-rollover event.

13.3.2.5.4 Hardware Time Stamp Push Event

There are four hardware time stamp inputs (HW1/4_TS_PUSH) that can cause hardware time stamp push events to be loaded into the Event FIFO. Each hardware time stamp input is internally connected to the PORTIMERPWM output of each timer as shown in Figure 4.

Figure 13-11. HW1/4_TSP_PUSH Connection

The event is loaded into the event FIFO on the rising edge of the timer, and the PORT_NUMBER field in the EVENT_HIGH register indicates the hardware time stamp input that caused the event.

Each hardware time stamp input must be asserted for at least 10 periods of the selected RCLK clock. Each input can be enabled or disabled by setting the respective bits in the ***CONTROL*** register.

Hardware time stamps are intended to be an extremely low frequency signals, such that the event FIFO does not overrun. Software must keep up with the event FIFO and ensure that there is no overrun, or events will be lost.

Copyright © 2011, Texas Instruments Incorporated

13.3.2.5.5 Ethernet Port Events

Packets transmitted or received on each Ethernet port can generate Ethernet Transmit Events or Ethernet Receive Events, respectively. The CPTS hardware will decode each packet to determine if it is a valid CPTS time sync event.

According to the IEEE 802.3 Ethernet standard, each Ethernet frame contains a 2-octet EtherType field to indicate which protocol is encapsulated in the PayLoad field, as shown in Figure 5(1). For standard time sync packets, this will contain the EtherType for the Precision Time Protocol (IEEE 1588), which is defined as 0x88F7. The CPTS hardware will compare this field to the **pX_ts_ltype** field in the **PX_TS_CTL** register, which should also be programmed to 0x88F7.

When a virtual LAN is used, an addition 4-octet 802.1Q tag is inserted in the Ethernet frame before the EtherType field, as shown in Figure 5(2). To indicate to the CPTS hardware that a virtual LAN is in use, the **pX_ts_tx_vlan_ltype1_en/pX_ts_rx_vlan_ltype1_en (**or **pX_ts_tx_vlan_ltype2_en/pX_ts_rx_vlan_ltype2_en)** enable bit must be set in the **PX_TS_CTL** register. The EtherType for the 802.1Q tag is defined as 0x8100, and the CTPS hardware will compare this value to the **pX_ts_vlan_ltype1** (or **pX_ts_vlan_ltype2** depending on which enable bit was set**)** field in the **PX_TS_VLAN_LTYPE** register, which should also be programmed to 0x8100.

When two stacked VLANs are used, two additional 4-octet 801.Q tags are inserted in the Ethernet frame before the EtherType field, as shown in Figure 5(3). In this case, both **pX_ts_vlan_ltype1** and **pX_ts_vlan_ltype2** must be enabled. The outer tag must match the value of the **pX_ts_vlan_ltype1** field, and the inner tag must match the value of the **pX_ts_vlan_ltype2** field.

Figure 13-12. Partial Ethernet-II frames showing register mapping of EtherTypes for a simple frame (1), a single 1Q tag added (2), and two 1Q tags added (3).

To enable transmit/receive event packets on a given Ethernet port, perform the following steps, where **X** is the port number:

- Set the **pX_ts_tx_en/pX_ts_rx_en** bit in the **PX_TS_CTL** register to enable transmit/receive event packets
- Configure the **PX_TS_SEQ_LTYPE** register:
  - Set the **pX_ts_ltype** field to 0x88F7, which corresponds to the Precision Time Protocol (IEEE 1588) EtherType.
  - Set the **pX_ts_seq_id_offset** field to 0x1E (d30), which is the sequence ID offset in the common message header given in the IEEE 1588 specification.
- To enable support for VLAN tagging (IEEE 802.1Q):
  - Set the **pX_ts_tx_vlan_ltype1_en/pX_ts_rx_vlan_ltype1_en** or **pX_ts_tx_vlan_ltype2_en/pX_ts_rx_vlan_ltype2_en** bit in the **PX_TS_CTL** register.
  - Set the **pX_ts_vlan_ltype1** or **pX_ts_vlan_ltype2** field (matching what was used in 3a) of the **PX_TS_VLAN_LTYPE** to 0x8100, which corresponds to the VLAN-tagged frame (IEEE 802.1Q) EtherType.
- To enable support for up to two stacked VLANs (IEEE 802.1ad):
  - Set the **pX_ts_tx_vlan_ltype1_en/pX_ts_rx_vlan_ltype1_en** and **pX_ts_tx_vlan_ltype2_en/pX_ts_rx_vlan_ltype2_en** bit in the **PX_TS_CTL** register.
  - Set the **pX_ts_vlan_ltype1** field of the **PX_TS_VLAN_LTYPE** register to match the EtherType of the outer tag.
  - Set the **pX_ts_vlan_ltype2** field of the **PX_TS_VLAN_LTYPE** register to 0x8100, which corresponds to the VLAN-tagged frame (IEEE 802.1Q) EtherType of the inner tag.
- Set the **pX_ts_msg_type_en** field of the **PX_TS_CTL** register to choose which types of time stamp messages will push events onto the Event FIFO. The following table enumerates the message types defined in the IEEE 1588-2008 specification.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Table 13-18. Values of messageType field

Message Type	Value (hex)
Sync	0
Delay_Req	1
Pdelay_Req	2
Pdelay_Resp	3
Reserved	4-7
Follow_Up	8
Delay_Resp	9
Pdelay_Resp_Follow_Up	A
Announce	B
Signaling	C
Management	D
Reserved	E-F

Once a transmitted or received packet is determined to be a valid time sync packet, the Ethernet Transmit Event or Ethernet Receive Event is loaded onto the Event FIFO. The **EVENT_HIGH** register contains the Message Type and Sequence ID values from the original time sync packet. The **EVENT_LOW** register contains the time stamp value when the packet arrived at the corresponding port.

13.3.2.6 Interrupt Handling

When an event is push onto the Event FIFO, an interrupt can be generated to indicate to software that a time sync event occurred. The following steps should be taken to process time sync events using interrupts:

- Enable the TS_PEND interrupt by setting the **TS_PEND_EN** bit of the **TS_Int_enable** register.
- Upon interrupt, read the **Event_Low** and **Event_High** register values.
- Set the EVENT_POP field (bit zero) of the **Event_Pop** register to pop the previously read value off of the event FIFO.
- Process the interrupt as required by the application software

Software has the option of processing more than a single event from the event FIFO in the interrupt

service routine in the following way:

- Enable the **TS_PEND** interrupt by setting the **TS_PEND_EN** bit of the **TS_Int_enable** register.
- Upon interrupt, read the **Event_Low** and **Event_High** register values.
- Set the **EVENT_POP** bit of the **Event_Pop** register to pop the previously read value off of the event FIFO.
- Wait for an amount of time greater than four **RCLK** periods plus four **VBUSP_CLK** periods.
- Read the **ts_pend_raw** bit in the **TS_Intstat_raw** register to determine if another valid event is in the event FIFO. If it is asserted then goto step 3. Otherwise goto step 6.
- Process the interrupt(s) as required by the application software

Software also has the option of disabling the interrupt and polling the **ts_pend_raw** bit of the **TS_Intstat_raw** register to determine if a valid event is on the event FIFO.

13.3.3 CPPI Buffer Descriptors

The buffer descriptor is a central part of the 3PSW Ethernet Subsytem and is how the application software describes Ethernet packets to be sent and empty buffers to be filled with incoming packet data.

Host Software sends and receives network frames via the CPPI 3.0 compliant host interface. The host interface includes module registers and host memory data structures. The host memory data structures are buffer descriptors and data buffers. Buffer descriptors are data structures that contain information about a single data buffer. Buffer descriptors may be linked together to describe frames or queues of frames for transmission of data and free buffer queues available for received data.

Note: The 8k bytes of Ethernet Subsystem CPPI RAM begin at address 0x4a102000 and end at 0x4a103FFF from the 3PSW perspective. The buffer descriptors programmed to access the CPPI RAM memory should use the address range from 0x4a102000.

13.3.3.1 TX Buffer Descriptors

A TX buffer descriptor is a contiguous block of four 32-bit data words aligned on a 32-bit word boundary.

13.3.3.1.1 Cppi Tx Data Word - 0

Next Descriptor Pointer

The next descriptor pointer points to the 32-bit word aligned memory address of the next buffer descriptor in the transmit queue. This pointer is used to create a linked list of buffer descriptors. If the value of this pointer is zero, then the current buffer is the last buffer in the queue. The software application must set this value prior to adding the descriptor to the active transmit list. This pointer is not altered by the EMAC.The value of pNext should never be altered once the descriptor is in an active transmit queue, unless its current value is NULL. If the pNext pointer is initially NULL, and more packets need to be queued for transmit, the software application may alter this pointer to point to a newly appended descriptor. The EMAC will use the new pointer value and proceed to the next descriptor unless the pNext value has already been read. In this latter case, the transmitter will halt on the transmit channel in question, and the software application may restart it at that time. The software can detect this case by checking for an end of queue (EOQ) condition flag on the updated packet descriptor when it is returned by the EMAC.

13.3.3.1.2 Cppi Tx Data Word - 1

Buffer Pointer

The byte aligned memory address of the buffer associated with the buffer descriptor. The host sets the **buffer_pointer**. The software application must set this value prior to adding the descriptor to the active transmit list. This pointer is not altered by the EMAC.

13.3.3.1.3 Cppi Tx Data Word - 2

Buffer _Offset

Buffer Offset – Indicates how many unused bytes are at the start of the buffer. A value of 0x0000 indicates that no unused bytes are at the start of the buffer and that valid data begins on the first byte of the buffer. A value of 0x000F (decimal 15) indicates that the first 15 bytes of the buffer are to be ignored by the port and that valid buffer data starts on byte 16 of the buffer. The host sets the buffer_offset value (which may be zero to the buffer length minus 1). Valid only on sop.

Buffer _Length

Buffer Length – Indicates how many valid data bytes are in the buffer. Unused or protocol specific bytes at the beginning of the buffer are not counted in the Buffer Length field. The host sets the buffer_length. The buffer_length must be greater than zero.

13.3.3.1.4 Cppi Tx Data Word – 3

Packet Length

Copyright © 2011, Texas Instruments Incorporated

Specifies the number of bytes in the entire packet. Offset bytes are not included. The sum of the buffer_length fields should equal the packet_length. Valid only on SOP. The packet length must be greater than zero. The packet data will be truncated to the packet length if the packet length is shorter than the sum of the packet buffer descriptor buffer lengths. A host error occurs if the packet length is greater than the sum of the packet buffer descriptor buffer lengths

Start of Packet (SOP) Flag

When set, this flag indicates that the descriptor points to a packet buffer that is the start of a new packet.In the case of a single fragment packet, both the SOP and end of packet (EOP) flags are set. Otherwise,the descriptor pointing to the last packet buffer for the packet sets the EOP flag. This bit is set by the software application and is not altered by the EMAC.

0 - Not start of packet buffer

1 - Start of packet buffer

End of Packet (EOP) Flag

When set, this flag indicates that the descriptor points to a packet buffer that is last for a given packet. In the case of a single fragment packet, both the start of packet (SOP) and EOP flags are set. Otherwise, the descriptor pointing to the last packet buffer for the packet sets the EOP flag. This bit is set by the software application and is not altered by the EMAC.

0 - Not end of packet buffer.

1 - End of packet buffer.

Ownership

When set this flag indicates that all the descriptors for the given packet (from SOP to EOP) are currently owned by the EMAC. This flag is set by the software application on the SOP packet descriptor before adding the descriptor to the transmit descriptor queue. For a single fragment packet, the SOP, EOP, and OWNER flags are all set. The OWNER flag is cleared by the EMAC once it is finished with all the descriptors for the given packet. Note that this flag is valid on SOP descriptors only.

0 - The packet is owned by the host

1 - The packet is owned by the port

EOQ

When set, this flag indicates that the descriptor in question was the last descriptor in the transmit queue for a given transmit channel, and that the transmitter has halted. This flag is initially cleared by the software application prior to adding the descriptor to the transmit queue. This bit is set by the EMAC when the EMAC identifies that a descriptor is the last for a given packet (the EOP flag is set), and there are no more descriptors in the transmit list (next descriptor pointer is NULL).

The software application can use this bit to detect when the EMAC transmitter for the corresponding channel has halted. This is useful when the application appends additional packet descriptors to a transmit queue list that is already owned by the EMAC. Note that this flag is valid on EOP descriptors only.

0 - The Tx queue has more packets to transfer.

1 - The Descriptor buffer is the last buffer in the last packet in the queue.

teardown_Complete

This flag is used when a transmit queue is being torn down, or aborted, instead of allowing it to be

transmitted. This would happen under device driver reset or shutdown conditions. The EMAC sets this bit in the SOP descriptor of each packet as it is aborted from transmission. Note that this flag is valid on SOP descriptors only. Also note that only the first packet in an unsent list has the TDOWNCMPLT flag set. Subsequent descriptors are not processed by the EMAC.

0 - The port has not completed the teardown process.

1 - The port has completed the commanded teardown process.

pass_crc

Copyright © 2011, Texas Instruments Incorporated

This flag is set by the software application in the SOP packet descriptor before it adds the descriptor to the transmit queue. Setting this bit indicates to the EMAC that the 4 byte Ethernet CRC is already present in the packet data, and that the EMAC should not generate its own version of the CRC.When the CRC flag is cleared, the EMAC generates and appends the 4-byte CRC. The buffer length and packet length fields do not include the CRC bytes. When the CRC flag is set, the 4-byte CRC is supplied by the software application and is already appended to the end of the packet data. The buffer length and packet length fields include the CRC bytes, as they are part of the valid packet data. Note that this flag is valid on SOP descriptors only.

0 – The CRC is not included with the packet data and packet length.

1 – The CRC is included with the packet data and packet length.

to_port

To Port – Port number to send the directed packet to. This field is set by the host. This field is valid on SOP. Directed packets go to the directed port, but an ALE lookup is performed to determine untagged egress in VLAN_AWARE mode.

1 – Send the packet to port 1 if to_port_en is asserted.

2 – Send the packet to port 2 if to_port_en is asserted.

To_port_enable

To Port Enable – Indicates when set that the packet is a directed packet to be sent to the to_port field port number. This field is set by the host. The packet is sent to one port only (index not mask). This bit is valid on SOP.

0 – not a directed packet

1 – directed packet

13.3.3.2 RX Buffer Descriptors

A RX buffer descriptor is a contiguous block of four 32-bit data words aligned on a 32-bit word boundary.

13.3.3.2.1 Cppi Rx Data Word – 0

next_descriptor_pointer

The 32-bit word aligned memory address of the next buffer descriptor in the RX queue. This is the mechanism used to reference the next buffer descriptor from the current buffer descriptor. If the value of this pointer is zero then the current buffer is the last buffer in the queue. The host sets the **next_descriptor_pointer**.

13.3.3.2.2 Cppi Rx Data Word – 1

buffer_pointer

The byte aligned memory address of the buffer associated with the buffer descriptor. The host sets the **buffer_pointer**.

13.3.3.2.3 Cppi Rx Data Word – 2

Buffer _Offset

Buffer Offset – Indicates how many unused bytes are at the start of the buffer. A value of 0x0000 indicates that there are no unused bytes at the start of the buffer and that valid data begins on the first byte of the buffer. A value of 0x000F (decimal 15) indicates that the first 15 bytes of the buffer are to be ignored by the port and that valid buffer data starts on byte 16 of the buffer. The port writes the **buffer_offset** with the value from the **rx_buffer_offset** register value. The host initializes the **buffer_offset** to zero for free buffers. The **buffer_length** must be greater than the **rx_buffer_offset** value. The buffer offset is valid only on **sop**.

Buffer _Length

Copyright © 2011, Texas Instruments Incorporated

Buffer Length – Indicates how many valid data bytes are in the buffer. Unused or protocol specific bytes at the beginning of the buffer are not counted in the Buffer Length field. The host initializes the **buffer_length**, but the port may overwrite the host initiated value with the actual buffer length value on SOP and/or EOP buffer descriptors. SOP buffer length values will be overwritten if the packet size is less than the size of the buffer or if the offset is nonzero. EOP buffer length values will be overwritten if the entire buffer is not filled up with data. The **buffer_length** must be greater than zero.

13.3.3.2.4 Cppi Rx Data Word – 3

Packet Length

Specifies the number of bytes in the entire packet. The packet length is reduced to 12-bits. Offset bytes are not included. The sum of the buffer_length fields should equal the packet_length. Valid only on SOP.

Start of Packet (SOP) Flag

When set, this flag indicates that the descriptor points to a packet buffer that is the start of a new packet.In the case of a single fragment packet, both the SOP and end of packet (EOP) flags are set. Otherwise, the descriptor pointing to the last packet buffer for the packet has the EOP flag set. This flag is initially cleared by the software application before adding the descriptor to the receive queue. This bit is set by the EMAC on SOP descriptors.

End of Packet (EOP) Flag

When set, this flag indicates that the descriptor points to a packet buffer that is last for a given packet. In the case of a single fragment packet, both the start of packet (SOP) and EOP flags are set. Otherwise, the descriptor pointing to the last packet buffer for the packet has the EOP flag set. This flag is initially cleared by the software application before adding the descriptor to the receive queue. This bit is set by the EMAC on EOP descriptors.

Ownership (OWNER) Flag

When set, this flag indicates that the descriptor is currently owned by the EMAC. This flag is set by the software application before adding the descriptor to the receive descriptor queue. This flag is cleared by the EMAC once it is finished with a given set of descriptors, associated with a received packet. The flag is updated by the EMAC on SOP descriptor only. So when the application identifies that the OWNER flag is cleared on an SOP descriptor, it may assume that all descriptors up to and including the first with the EOP flag set have been released by the EMAC. (Note that in the case of single buffer packets, the same descriptor will have both the SOP and EOP flags set.)

End of Queue (EOQ) Flag

When set, this flag indicates that the descriptor in question was the last descriptor in the receive queue for a given receive channel, and that the corresponding receiver channel has halted. This flag is initially cleared by the software application prior to adding the descriptor to the receive queue. This bit is set by the EMAC when the EMAC identifies that a descriptor is the last for a given packet received (also sets the EOP flag), and there are no more descriptors in the receive list (next descriptor pointer is NULL).The software application can use this bit to detect when the EMAC receiver for the corresponding channel has halted. This is useful when the application appends additional free buffer descriptors to an active receive queue. Note that this flag is valid on EOP descriptors only.

Teardown Complete (TDOWNCMPLT) Flag

This flag is used when a receive queue is being torn down, or aborted, instead of being filled with received data. This would happen under device driver reset or shutdown conditions. The EMAC sets this bit in the descriptor of the first free buffer when the tear down occurs. No additional queue processing is performed.

Pass CRC (PASSCRC) Flag

This flag is set by the EMAC in the SOP buffer descriptor if the received packet includes the 4-byte CRC.This flag should be cleared by the software application before submitting the descriptor to the receive queue.

Long (Jabber) Flag

Copyright © 2011, Texas Instruments Incorporated

This flag is set by the EMAC in the SOP buffer descriptor, if the received packet is a jabber frame and was not discarded because the RX_CEF_EN bit was set in the MacControl. Jabber frames are frames that exceed the RXMAXLEN in length, and have CRC, code, or alignment errors.

Short (Fragment) Flag

This flag is set by the EMAC in the SOP buffer descriptor, if the received packet is only a packet fragment and was not discarded because the RX_CSF_EN bit was set in the MacControl.

Control Flag

This flag is set by the EMAC in the SOP buffer descriptor, if the received packet is an EMAC control frame and was not discarded because the RX_CMF_EN bit was set in the MacControl.

Overrun Flag

This flag is set by the EMAC in the SOP buffer descriptor, if the received packet was aborted due to a receive overrun.

Pkt_error Flag

Packet Contained Error on Ingress –

00 – no error

01 – CRC error on ingress

10 – Code error on ingress

11 – Align error on ingress

rx_vlan_encap

VLAN Encapsulated Packet – Indicates when set that the packet data contains a 32-bit VLAN header word that is included in the packet byte count. This field is set by the port to be the value of the CPSW control register **rx_vlan_encap** bit

from_port

From Port – Indicates the port number that the packet was received on (ingress to the switch).

13.3.4 MDIO

The MII Management I/F module implements the 802.3 serial management interface to interrogate and control two Ethernet PHYs simultaneously using a shared two-wire bus. Two user access registers to control and monitor up to two PHYs simultaneously.

13.3.4.1 MII Management Interface Frame Formats

The following tables show the read and write format of the 32-bit MII Management interface frames, respectively.

Table 13-19. MDIO Read Frame Format

Preamble	Start Delimiter	Operation Code	PHY Address	Register Address	Turnaround	Data
0xFFFFFFFF	01	10	AAAAA	RRRRR	Z0	DDDD.DDDD.DDDD.DDDD

Table 13-20. MDIO Write Frame Format

Preamble	Start Delimiter	Operation Code	PHY Address	Register Address	Turnaround	Data
0xFFFFFFFF	01	00	AAAAA	RRRRR	10	DDDD.DDDD.DDDD.DDDD

Copyright © 2011, Texas Instruments Incorporated

DRAFT ONLY

The default or idle state of the two wire serial interface is a logic one. All tri-state drivers should be disabled and the PHY's pull-up resistor will pull the **MDIO** line to a logic one. Prior to initiating any other transaction, the station management entity shall send a preamble sequence of 32 contiguous logic one bits on the **MDIO** line with 32 corresponding cycles on **MDCLK** to provide the PHY with a pattern that it can use to establish synchronization. A PHY shall observe a sequence of 32 contiguous logic one bits on **MDIO** with 32 corresponding **MDCLK** cycles before it responds to any other transaction.

Preamble

The start of a frame is indicated by a preamble, which consists of a sequence of 32 contiguous bits all of which are a "1". This sequence provides the PHY a pattern to use to establish synchronization.

Start Delimiter

The preamble is followed by the start delimiter which is indicated by a "01" pattern. The pattern assures transitions from the default logic one state to zero and back to one.

Operation Code

The operation code for a read is "10", while the operation code for a write is a "00".

PHY Address

The PHY address is 5 bits allowing 32 unique values. The first bit transmitted is the MSB of the PHY address.

Register Address

The Register address is 5 bits allowing 32 registers to be addressed within each PHY. Refer to the 10/100 PHY address map for addresses of individual registers.

Turnaround

An idle bit time during which no device actively drives the MDIO signal shall be inserted between the register address field and the data field of a read frame in order to avoid contention. During a read frame, the PHY shall drive a zero bit onto MDIO for the first bit time following the idle bit and preceding the Data field. During a write frame, this field shall consist of a one bit followed by a zero bit.

Data

The Data field is 16 bits. The first bit transmitted and received is the MSB of the data word.

13.3.4.2 Functional description

The MII Management I/F will remain idle until enabled by setting the **enable** bit in the **MDIOControl** register. The MII Management I/F will then continuously poll the link status from within the Generic Status Register of all possible 32 PHY addresses in turn recording the results in the **MDIOLink** register. The **linksel** bit in the **MDIOUserPhySel** register determines the status input that is used. A change in the link status of the two PHYs being monitored will set the appropriate bit in the **MDIOLinkIntRaw** register and the **MDIOLinkIntMasked** register, if enabled by the **linkint_enable** bit in the **MDIOUserPhySel** register.

The **MDIOAlive** register is updated by the MII Management I/F module if the PHY acknowledged the read of the generic status register. In addition, any PHY register read transactions initiated by the host also cause the **MDIOAlive** register to be updated.

At any time, the host can define a transaction for the MII Management interface module to undertake using the **data, phyadr, regadr,** and **write** fields in a **MDIOUserAccess** register. When the host sets the **go** bit in this register, the MII Management interface module will begin the transaction without any further intervention from the host. Upon completion, the MII Management interface will clear the **go** bit and set the **userintraw** bit in the **MDIOUserIntRaw** register corresponding to the **MDIOUserAccess** register being used. The corresponding bit in the **MDIOUserIntMasked** register may also be set depending on the mask setting in the **MDIOUserIntMaskSet** and **MDIOUserIntMaskClr** registers. A round-robin arbitration scheme is used to schedule transactions which may queued by the host in different **MDIOUserAccess** registers. The host should check the status of the **go** bit in the **MDIOUserAccess** register before initiating a new transaction to ensure that the previous transaction has completed. The host can use the **ack** bit in the **MDIOUserAccess** register to determine the status of a read transaction.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

It is necessary for software to use the MII Management interface module to setup the auto-negotiation parameters of each PHY attached to a MAC port, retrieve the negotiation results, and setup the **MACControl** register in the corresponding MAC.

13.3.5 Interrupts

The 3Port Switch Ethernet Subsystem generates 4 interrupt events.

13.3.5.1 Receive Packet Completion Pulse Interrupt (RX_PULSE)

The RX_PULSE interrupt is a pulse interrupt selected from the 3PSW RX_PEND [7:0] interrupts. The receive DMA controller has eight channels with each channel having a corresponding (RX_PEND[7:0]).

The following steps will enable the receive packet completion interrupt.

- Enable the required channel interrupts of the DMA engine by setting 1 to the appropriate bit in the RX_INTMASK_SET register.
- The receive completion interrupt(s) to be routed to RX_PULSE is selected by setting one or more bits in the receive interrupt enable register RX_EN . The masked interrupt status can be read in the address location of RX_STAT bit in the receive status register.

When the 3PSW completes a packet reception, the subsystem issues an interrupt to the CPU by writing the packet's last buffer descriptor address to the appropriate channel queue's receive completion pointer located in the state RAM block. The interrupt is generated by the write when enabled by the interrupt mask, regardless of the value written.

Upon interrupt reception, the CPU processes one or more packets from the buffer chain and then

acknowledges one or more interrupt(s) by writing the address of the last buffer descriptor processed to the queue's associated receive completion pointer (RX*n*_CP) in the receive DMA state RAM.

Upon reception of an interrupt, software should perform the following:

- Read the RX_STAT bit address location to determine which channel(s) caused the interrupt.
- Process received packets for the interrupting channel(s).
- Write the 3PSW completion pointer(s) (RX*n*_CP). The data written by the host (buffer descriptor address of the last processed buffer) is compared to the data in the register written by the subsystem (address of last buffer descriptor used by the subsystem). If the two values are not equal (which means that the 3PSW has received more packets than the CPU has processed), the receive packet completion interrupt signal remains asserted. If the two values are equal (which means that the host has processed all packets that the system has received), the pending interrupt is de-asserted. The value that the 3PSW is expecting is found by reading the receive channel*n* completion pointer register (RX*n*_CP).
- Write the value 1h to the CPDMA_EOI_VECTOR register.

To disable the interrupt:

- The eight channel interrupts may be individually disabled by writing to 1 the appropriate bit in the RX_INTMASK_CLEAR
- The receive completion pulse interrupt could be disabled by clearing to 0 all the bits of the RX_EN.

The software could still poll for the RX_INTSTAT_RAW and RX_INTSTAT_MASKED registers if the corresponding interrupts are enabled.

13.3.5.2 Transmit Packet Completion Pulse Interrupt (TX_PULSE)

The TX_PULSE interrupt is a pulse interrupt selected from the 3PSW TX_PEND [7:0] interrupts. The transmit DMA controller has eight channels with each channel having a corresponding (TX_PEND[7:0]).

To enable the transmit packet completion interrupt:

- Enable the required channel interrupts of the DMA engine by setting 1 to the appropriate bit in the TX_INTMASK_SET register.
- The transmit completion interrupt(s) to be routed to TX_PULSE is selected by setting one or more bits in the transmit interrupt enable register TX_EN .The masked interrupt status can be read in the address location of TX_STAT bit in the transmit status register.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

When the 3PSW completes the transmission of a packet, the 3PSW subsystem issues an interrupt to the CPU by writing the packet's last buffer descriptor address to the appropriate channel queue's transmit completion pointer located in the state RAM block. The interrupt is generated by the write when enabled by the interrupt mask, regardless of the value written.

Upon receiving an interrupt, software should perform the following:

- Read the TX_STAT bit address location to determine which channel(s) caused the interrupt
- Process received packets for the interrupting channel(s).
- Write the 3PSW completion pointer(s) (TX*n*_CP). The data written by the host (buffer descriptor address of the last processed buffer) is compared to the data in the register written by the 3PSW (address of last buffer descriptor used by the 3PSW). If the two values are not equal (which means that the 3PSW has transmitted more packets than the CPU has processed), the transmit packet completion interrupt signal remains asserted. If the two values are equal (which means that the host has processed all packets that the subsystem has transferred), the pending interrupt is cleared. The value that the 3PSW is expecting is found by reading the transmit channel*n* completion pointer register (TX*n*_CP).
- Write the 2h to the CPDMA_EOI_VECTOR register.

To disable the interrupt:

- The eight channel interrupts may be individually disabled by writing to 1 the appropriate bit in the TX_INTMASK_CLEAR.
- The receive completion pulse interrupt could be disabled by clearing to 0 all the bits of the TX_EN. The software could still poll for the TX_INTSTAT_RAW and TX_INTSTAT_MASKED registers if the corresponding interrupts are enabled.

13.3.5.3 Receive Threshold Pulse Interrupt (RX_THRESH_PULSE)

The RX_THRESH_PULSE interrupt is an immediate (non-paced) pulse interrupt selected from the CPSW_3G RX_THRESH_PEND[7:0] interrupts. The receive DMA controller has eight channels with each channel having a corresponding threshold pulse interrupt (RX_THRESH_PEND [7:0]).

To enable the receive threshold pulse Interrupt:

- Enable the required channel interrupts of the DMA engine by setting 1 to the appropriate bit in the RX_INTMASK_SET register.
- The receive threshold interrupt(s) to be routed to RX_THRESH_PULSE is selected by setting one or more bits in the receive threshold interrupt enable register RX_THRESH_EN. The masked interrupt status can be read in the address location of RX_THRESH_STAT bit in the receive threshold status register.

The RX_THRESH_PULSE is asserted when enabled when the channel's associated free buffer count RX*n*_FREEBUFFER is less than or equal to the corresponding RX*n*_PENDTHRESH register.

Upon receiving an interrupt, software should perform the following:

- Read the RX_THRESH_STAT bit address location to determine which channel(s) caused the interrupt.
- Process the received packets in order to add more buffers to any channel that is below the threshold value.
- Write the CPSW_3G completion pointer(s).
- Write the value 0h to the CPDMA_EOI_VECTOR register.

The threshold pulse interrupt is an immediate interrupt intended to indicate that software should immediately process packets to preclude an overrun condition from occurring for the particular channels.

To disable the interrupt:

- The eight channel receive threshold interrupts may be individually disabled by writing to 1 the appropriate bit in the RX_INTMASK_CLEAR register.
- The receive threshold pulse interrupt could be disabled by clearing to Zero the corresponding bits of the RX_THRESH_EN. The software could still poll for the RX_INTSTAT_RAW and INTSTAT_MASKED registers if the corresponding interrupts are enabled.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

13.3.5.4 Miscellaneous Pulse Interrupt (MISC_PULSE)

The MISC_PULSE interrupt is an immediate pulse interrupt selected from the miscellaneous interrupts (**EVNT_PEND**,STAT_PEND, HOST_PEND, MDIO_LINKINT, MDIO_USERINT). The miscellaneous interrupt(s) is selected by setting one or more bits in the **Misc_En[4:0]** register. The masked interrupt status can be read in the **Misc_Stat[4:0]** address location. Upon reception of an interrupt, software should perform the following:

- Read the **Misc_Stat[4:0]** address location to determine which caused the interrupt.
- Process the interrupt.
- Write the appropriate value (0x3) to the CPDMA_**EOI_VECTOR**
- **MDIO_LINTINT[1]** and **MDIO_USERINT[1]** are unused.

13.3.5.4.1 EVNT_PEND (CPTS_PEND) Interrupt

See CPTS TIME SYNC for more details on this interrupt.

13.3.5.4.2 Statistics Interrupt

The statistics level interrupt (**STAT_PEND)** will be asserted if enabled when any statistics value is greater than or equal to 0x80000000. The statistics interrupt is cleared by writing to decrement all statistics values greater than 0x80000000 (such that their new values are less than 0x80000000). The raw and masked statistics interrupt status may be read by reading the TX_**IntStat_Raw** and TX_**IntStat_Masked** registers respectively

13.3.5.4.3 Host Error Interrupt

The host error interrupt (HOST_PEND) will be asserted if enabled when a host error is detected during transmit or receive CPDMA transactions. The host error interrupt is intended for software debug, and is cleared by a warm reset or a system reset. The raw and masked statistics interrupt status can be read by reading the TX_INTSTAT_RAW and TXINTSTAT_MASKED registers, respectively.

The following list shows the transmit host error conditions:

- SOP error
- OWNERSHIP bit not set in SOP buffer
- next buffer descriptor pointer without EOP set to 0
- buffer pointer set to 0
- buffer length set to 0
- packet length error

The receive host error conditions are show in the following list:

- Ownership bit not set in input buffer.
- Zero buffer pointer.
- Zero buffer Length on non-SOP descriptor.
- SOP buffer length not greater than offset.

The host error interrupt is disabled by clearing to 0 the appropriate bit in the CPDMA_INTMASK_CLEAR register.

13.3.5.4.4 MDIO Interrupts

MDIO_LINKINT is set if there is a change in the link state of the PHY corresponding to the address in the PHYADDRMON field of the MDIOUSERPHYSEL*n* register and the corresponding LINKINTENB bit is set.The MDIO_LINKINT event is also captured in the MDIOLINKINTMASKED register.When the GO bit in the MDIOUSERREGISTER*n* registers transitions from 1 to 0, indicating the completion of a user access, and the corresponding USERINTMASKSET bit in the

MDIOUSERINTMASKSET register is set, the MDIO_USERINT signal is asserted 1. The MDIO_USERINT event is also captured in the MDIOUSERINTMASKED register.

Copyright © 2011, Texas Instruments Incorporated

DRAFT ONLY

To enable the miscellaneous pulse interrupt:

The miscellaneous interrupt(s) is selected by setting one or more bits in the miscellaneous interrupt enable register (MISC_EN).

- The Statistics interrupt is enabled by setting to 1 the STAT_INT_MASK bit in the CPDMAINTMASK_SET register.
- The HOST_PEND is enabled by setting to 1 the HOST_ERR_INTMASK in the CPDMAINTMASK_SET register.

Upon receiving of an interrupt, software should perform the following:

- Read the MISC_STAT bit address location to determine the source of the interrupt.
- Process the interrupt.
- Write the value 3h to the CPDMA_EOI_VECTOR register.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

13.3.6 Interrupt Pacing

The receive and transmit pulse interrupts can be paced. The receive threshold and miscellaneous interrupts are not paced. The Interrupt pacing feature limits the number of interrupts that occur during a given period of time. For heavily loaded systems in which interrupts can occur at a very high rate (e.g. 148,800 packets per second for Ethernet), the performance benefit is significant due to minimizing the overhead associated with servicing each interrupt. Interrupt pacing increases the CPU cache hit ratio by minimizing the number of times that large interrupt service routines are moved to and from the CPU instruction cache.

Each CPU receive and transmit pulse interrupt contains an interrupt pacing sub-block (six total). Each sub-block is disabled by default allowing the selected interrupt inputs to pass through unaffected. The interrupt pacing module counts the number of interrupts that occur over a 1ms interval of time. At the end of each 1ms interval, the current number of interrupts is compared with a target number of interrupts (specified by the associated maximum number of interrupts register).

Based on the results of the comparison, the length of time during which interrupts are blocked is dynamically adjusted. The 1ms interval is derived from a 4us pulse that is created from a prescale counter whose value is set in the **int_prescale** value in the **Int_Control** register. The **int_prescale** value should be written with the number of **VBUSP_CLK** periods in 4us. The pacing timer determines the interval during which interrupts are blocked and decrements every 4us. It is reloaded each time a zero count is reached. The value loaded into the pacing timer is calculated by hardware every 1ms according to the following algorithm:

```
if (intr_count > 2*intr_max)
pace_timer = 255;
else if (intr_count > 1.5*intr_max)
pace_timer = last_pace_timer*2 + 1;
else if (intr_count > 1.0*intr_max)
pace_timer = last_pace_timer + 1;
else if (intr_count > 0.5*intr_max)
pace_timer = last_pace_timer - 1;
else if (intr_count != 0)
pace_timer = last_pace_timer/2;
else
pace_timer = 0;
```

If the rate of interrupt inputs is much less than the target interrupt rate specified in the associated maximum interrupts register, then the interrupt is not blocked. If the interrupt rate is greater than the target rate, the interrupt will be “paced” at the rate specified in the interrupt maximum register. The interrupt maximum register should be written with a value between 2 and 63 inclusive indicating the target number of interrupts per milli-second.

13.3.7 Reset Isolation

Reset isolation for the Ethernet switch on Device is that the switch function of the ethernet IP remains active even in case of all device resets except for POR pin reset and ICEPICK COLD reset. Packet traffic to/from the 3PSW host will be flushed/dropped, but the ethernet switch will remain operational for all traffic between external devices on the switch even though the device is under-going a device reset.Pin mux configuration for ethernet related IO and reference clocks needed by the Ethernet switch IP to be active is controlled by a protected control module bit. If reset isolation is enabled, then only a POR pin or ICEPICK COLD reset event should fully reset the Ethernet switch IP including the actual switch and also the reference clocks and pin mux control specifically associated with the Ethernet IP.

13.3.7.1 Modes of Operation

The device has two modes of operation concerning the reset of the 3PSW Ethernet switch.

The mode is controlled by the ISO_CONTROL bit in **RESET_ISO** register of the **Device control module**.This bit should default to '0'. Any modification of this bit first requires writing an unlock pattern to lock register in Device control module. After modification, the bit should again be locked by writing appropriate value to the lock register (see Device control module for details). Writes to the ISO_CONTROL bit and to the lock register must all be supervisor mode writes.

Mode1: ISO_CONTROL=0 (reset isolation disabled)

- This mode is selected when ISO_CONTROL bit of control module is = 0. This should be the default state of the bit after control module reset.
- Upon any device level resets, the entire CPSW_3GSS_R IP, SATA_SS, SATA SERDES pll, L3/L4, control module (including all pin mux control and the ISO_CONTROL bit) is immediately reset.

Mode2: ISO_CONTROL=1 (reset isolation enabled)

- This mode is selected when ISO_CONTROL bit of control module is = 1.
- Upon any device reset source other than POR pin or ICEPICK cold (so this includes SW global cold, any watchdog reset, warm RESETn pin, ICEPICK warm, SW global warm or security violation), the following should be true:
  - The CPSW_3GSS_R is put into ‘isolate’ mode and non-switch related portions of the IP are reset.
  - The 50-MHz and 125-MHz reference clocks to the 3PSW Ethernet Subsystem remains active throughout the entire reset condition.
  - The control for pin multiplexing for all of the signals should maintain their current configuration throughout the entire reset condition.
  - The reset isolated logic inside 3PSW Ethernet Subsystem IP which maintains the switch functionality
  -
- Upon any cold reset sources, the entire 3PSW Ethernet Subsystem, SATA SERDES pll, control module (including all pin mux control and the ISO_CONTROL bit itself) is reset.

For more details on the register configuration, see the Device Control Module reset_iso register.

13.3.8 CPSW_3G Network Statistics

The CPSW_3G has a set of statistics that record events associated with frame traffic on selected switch ports. The statistics values are cleared to zero 38 clocks after the rising edge of **VBUSP_RST_N**. When one or more port enable bits **(stat_port_en[2:0])** are set, all statistics registers are write to decrement. The value written will be subtracted from the register value with the result being stored in the register. If a value greater than the statistics value is written, then zero will be written to the register (writing 0xffffffff will clear a statistics location). When all port enable bits are cleared to zero, all statistics registers are read/write (normal write direct, so writing 0x00000000 will clear a statistics location). All write accesses must be 32-bit accesses. In the below statistics descriptions, “the port” refers to any enabled port (with a corresponding set **stat_port_en[2:0]** bit).

The statistics interrupt (**STAT_PEND)** will be issued if enabled when any statistics value is greater than or equal to 0x80000000. The statistics interrupt is removed by writing to decrement any statistics value greater than 0x80000000. The statistics are mapped into internal memory space and are 32-bits wide. All statistics rollover from 0xFFFFFFFF to 0x00000000.

See the Section CPSW Memory Map for more details on the register description.

13.4 Software Operation

13.4.1 Transmit Operation

After reset the host must write zeroes to all Tx DMA State head descriptor pointers. The Tx port may then be enabled. To initiate packet transmission the host constructs transmit queues in memory (one or more packets for transmission) and then writes the appropriate Tx DMA state head descriptor pointers. For each buffer added to a transmit queue, the host must initialize the Tx buffer descriptor values as follows:

1. Write the Next Descriptor Pointer with the 32-bit aligned address of the next descriptor in the queue (zero if last descriptor).
2. Write the Buffer Pointer with the byte aligned address of the buffer data.
3. Write the Buffer Length with the number of bytes in the buffer.
4. Write the Buffer Offset with the number of bytes in the offset to the data (nonzero with SOP only).
5. Set the SOP, EOP, and Ownership bits as appropriate.
6. Clear the End Of Queue bit.

The port begins Tx packet transmission on a given channel when the host writes the channel's Tx queue head descriptor pointer with the address of the first buffer descriptor in the queue (nonzero value). Each channel may have one or more queues, so each channel may have one or more head descriptor pointers. The first buffer descriptor for each Tx packet must have the Start of Packet (SOP) bit and the Ownership bit set to one by the host. The last buffer descriptor for each Tx packet must have the End of Packet (EOP) bit set to one by the host.

The port will transmit packets until all queued packets have been transmitted and the queue(s) are empty. When each packet transmission is complete, the port will clear the Ownership bit in the packet's SOP buffer descriptor and issue an interrupt to the host by writing the packet's last buffer descriptor address to the queue's Tx DMA State Completion Pointer. The interrupt is generated by the write, regardless of the value written.

When the last packet in a queue has been transmitted, the port sets the End Of Queue bit in the EOP buffer descriptor, clears the Ownership bit in the SOP Descriptor, zeroes the appropriate DMA state head descriptor pointer, and then issues a Tx interrupt to the host by writing to the queue's associated Tx completion pointer (address of the last buffer descriptor processed by the port). The port issues a maskable level interrupt (which may then be routed through external interrupt control logic to the host).

On interrupt from the port, the host processes the buffer queue, detecting transmitted packets by the status of the Ownership bit in the SOP buffer descriptor. If the Ownership bit is cleared to zero, then the packet has been transmitted and the host may reclaim the buffers associated with the packet. The host continues queue processing until the end of the queue or until a SOP buffer descriptor is read that contains a set Ownership bit indicating that the packet transmission is not complete.

The host determines that all packets in the queue have been transmitted when the last packet in the queue has a cleared Ownership bit in the SOP buffer descriptor, the End of Queue bit is set in the last packet EOP buffer descriptor, and the Next Descriptor Pointer of the last packet EOP buffer descriptor is zero. The host acknowledges an interrupt by writing the address of the last buffer descriptor to the queue's associated Tx Completion Pointer in the Tx DMA State.

If the host written buffer address value is different from the buffer address written by the port, then the level interrupt remains asserted. If the host written buffer address value is equal to the port written value, then the level interrupt is deasserted. The port write to the completion pointer actually stores the value in the state register (ram). The host written value is actually not written to the register location. The host written value is compared to the register contents (which was written by the port) and if the two values are equal, the interrupt is removed, otherwise the interrupt remains asserted. The host may process multiple packets previous to acknowledging an interrupt, or the host may acknowledge interrupts for every packet.

A misqueued packet condition may occur when the host adds a packet to a queue for transmission as the port finishes transmitting the previous last packet in the queue. The misqueued packet is detected by the host when queue processing detects a cleared Ownership bit in the SOP buffer descriptor, a set End of Queue bit in the EOP buffer descriptor, and a nonzero Next Descriptor Pointer in the EOP buffer descriptor.

Copyright © 2011, Texas Instruments Incorporated

A misqueued packet means that the port read the last EOP buffer descriptor before the host added the new last packet to the queue, so the port determined queue empty just before the last packet was added. The host corrects the misqueued packet condition by initiating a new packet transfer for the misqueued packet by writing the misqueued packet's SOP buffer descriptor address to the appropriate DMA State Tx Queue head Descriptor Pointer.

The host may add packets to the tail end of an active Tx queue at any time by writing the Next Descriptor Pointer to the current last descriptor in the queue. If a Tx queue is empty (inactive), the host may initiate packet transmission at any time by writing the appropriate Tx DMA State head descriptor pointer.

The host software should always check for and reinitiate transmission for misqueued packets during queue processing on interrupt from the port. In order to preclude software underrun, the host should avoid adding buffers to an active queue for any Tx packet that is not complete and ready for transmission.

The port determines that a packet is the last packet in the queue by detecting the End of Packet bit set with a zero Next Descriptor Pointer in the packet buffer descriptor. If the End of Packet bit is set and the Next Descriptor Pointer is nonzero, then the queue still contains one or more packets to be transmitted. If the EOP bit is set with a zero Next Descriptor Pointer, then the port will set the EOQ bit in the packet's EOP buffer descriptor and then zero the appropriate head descriptor pointer previous to interrupting the port (by writing the completion pointer) when the packet transmission is complete.

Figure 13-13.

13.4.2 Receive Operation

Figure 13-14.

After reset the host must write zeroes to all Rx DMA State head descriptor pointers. The Rx port may then be enabled. To initiate packet reception, the host constructs receive queues in memory and then writes the appropriate Rx DMA state head descriptor pointer. For each Rx buffer descriptor added to the queue, the host must initialize the Rx buffer descriptor values as follows:

- Write the Next Descriptor Pointer with the 32-bit aligned address of the next descriptor in the queue (zero if last descriptor)
- Write the Buffer Pointer with the byte aligned address of the buffer data
- Clear the Offset field
- Write the Buffer Length with the number of bytes in the buffer
- Clear the SOP, EOP, and EOQ bits
- Set the Ownership bit

The host enables packet reception on a given channel by writing the address of the first buffer descriptor in the queue (nonzero value) to the channel's head descriptor pointer in the channel's Rx DMA state. When packet reception begins on a given channel, the port fills each Rx buffer with data in order starting with the first buffer and proceeding through the Rx queue. If the Buffer Offset in the Rx DMA State is nonzero, then the port will begin writing data after the offset number of bytes in the SOP buffer. The port performs the following operations at the end of each packet reception:

- Overwrite the buffer length in the packet's EOP buffer descriptor with the number of bytes actually received in the packet's last buffer. The host initialized value is the buffer size. The overwritten value will be less than or equal to the host initialized value.
- Set the EOP bit in the packet's EOP buffer descriptor.
- Set the EOQ bit in the packet's EOP buffer descriptor if the current packet is the last packet in the queue.
- Overwrite the packet's SOP buffer descriptor Buffer Offset with the Rx DMA state value (the host initialized the buffer descriptor Buffer Offset value to zero). All non SOP buffer descriptors must have a zero Buffer Offset initialized by the host.
- Overwrite the packet's SOP buffer descriptor buffer length with the number of valid data bytes in the buffer. If the buffer is filled up, the buffer length will be the buffer size minus buffer offset.

Copyright © 2011, Texas Instruments Incorporated

- Set the SOP bit in the packet's SOP buffer descriptor.
- Write the SOP buffer descriptor Packet Length field.
- Clear the Ownership bit in the packet's SOP buffer descriptor.
- Issue an Rx host interrupt by writing the address of the packet's last buffer descriptor to the queue's Rx DMA State Completion Pointer. The interrupt is generated by the write to the Rx DMA State Completion Pointer address location, regardless of the value written.

On interrupt the host processes the Rx buffer queue detecting received packets by the status of the Ownership bit in each packet's SOP buffer descriptor. If the Ownership bit is cleared then the packet has been completely received and is available to be processed by the host.

The host may continue Rx queue processing until the end of the queue or until a buffer descriptor is read that contains a set Ownership bit indicating that the next packet's reception is not complete. The host determines that the Rx queue is empty when the last packet in the queue has a cleared Ownership bit in the SOP buffer descriptor, a set End of Queue bit in the EOP buffer descriptor, and the Next Descriptor Pointer in the EOP buffer descriptor is zero.

A misqueued buffer may occur when the host adds buffers to a queue as the port finishes the reception of the previous last packet in the queue. The misqueued buffer is detected by the host when queue processing detects a cleared Ownership bit in the SOP buffer descriptor, a set End of Queue bit in the EOP buffer descriptor, and a nonzero Next Descriptor Pointer in the EOP buffer descriptor.

A misqueued buffer means that the port read the last EOP buffer descriptor before the host added buffer descriptor(s) to the queue, so the port determined queue empty just before the host added more buffer descriptor(s). In the transmit case, the packet transmission is delayed by the time required for the host to determine the condition and reinitiate the transaction, but the packet is not actually lost. In the receive case, receive overrun condition may occur in the misqueued buffer case.

If a new packet reception is begun during the time that the port has determined the end of queue condition, then the received packet will overrun (start of packet overrun). If the misqueued buffer occurs during the middle of a packet reception then middle of packet overrun may occur. If the misqueued buffer occurs after the last packet has completed, and is corrected before the next packet reception begins, then overrun will not occur. The host acts on the misqueued buffer condition by writing the added buffer descriptor address to the appropriate Rx DMA State Head Descriptor Pointer.

13.4.3 Initializing the MDIO Module

The following steps are performed by the application software or device driver to initialize the MDIO device:

1. 1. Configure the PREAMBLE and CLKDIV bits in the MDIO control register (MDIOCONTROL).
2. Enable the MDIO module by setting the ENABLE bit in MDIOCONTROL.
3. The MDIO PHY alive status register (MDIOALIVE) can be read in polling fashion until a PHY connected to the system responded, and the MDIO PHY link status register (MDIOLINK) can determine whether this PHY already has a link.
4. Setup the appropriate PHY addresses in the MDIO user PHY select register (MDIOUSERPHYSEL*n*), and set the LINKINTENB bit to enable a link change event interrupt if desirable.

- If an interrupt on general MDIO register access is desired, set the corresponding bit in the MDIO user command complete interrupt mask set register (MDIOUSERINTMASKSET) to use the MDIO user access register (MDIOUSERACCESS*n*). Since only one PHY is used in this device, the application software can use one MDIOUSERACCESS*n* to trigger a completion interrupt; the other MDIOUSERACCESS*n* is not setup.

13.4.4 Writing Data to a PHY Register

The MDIO module includes a user access register (MDIOUSERACCESS*n*) to directly access a specified PHY device.To write a PHY register, perform the following:

1. Check to ensure that the GO bit in the MDIO user access register (MDIOUSERACCESS*n*) is cleared.

2. Write to the GO, WRITE, REGADR, PHYADR, and DATA bits in MDIOUSERACCESS*n* corresponding to the PHY and PHY register you want to write.

Copyright © 2011, Texas Instruments Incorporated

3. The write operation to the PHY is scheduled and completed by the MDIO module. Completion of the write operation can be determined by polling the GO bit in MDIOUSERACCESS*n* for a 0.

4. Completion of the operation sets the corresponding USERINTRAW bit (0 or 1) in the MDIO user command complete interrupt register (MDIOUSERINTRAW) corresponding to USERACCESS*n* used. If interrupts have been enabled on this bit using the MDIO user command complete interrupt mask set register (MDIOUSERINTMASKSET), then the bit is also set in the MDIO user command complete interrupt register (MDIOUSERINTMASKED) and an interrupt is triggered on the CPU.

13.4.5 Reading Data from a PHY Register

The MDIO module includes a user access register (MDIOUSERACCESS*n*) to directly access a specified PHY device. To read a PHY register, perform the following:

1. Check to ensure that the GO bit in the MDIO user access register (MDIOUSERACCESS*n*) is cleared.

2. Write to the GO, REGADR, and PHYADR bits in MDIOUSERACCESS*n* corresponding to the PHY and PHY register you want to read.

3. The read data value is available in the DATA bits in MDIOUSERACCESS*n* after the module completes the read operation on the serial bus. Completion of the read operation can be determined by polling the GO and ACK bits in MDIOUSERACCESS*n*. After the GO bit has cleared, the ACK bit is set on a successful read.

4. Completion of the operation sets the corresponding USERINTRAW bit (0 or 1) in the MDIO user command complete interrupt register (MDIOUSERINTRAW) corresponding to USERACCESS*n* used. If interrupts have been enabled on this bit using the MDIO user command complete interrupt mask set register (MDIOUSERINTMASKSET), then the bit is also set in the MDIO user command complete interrupt register (MDIOUSERINTMASKED) and an interrupt is triggered on the CPU.

13.4.6 Initialization and Configuration of CPSW

To configure the 3PSW Ethernet Subsystem for operation the host must perform the following:

- Select the Interface (GMII/RGMII/MII) Mode. (Refer to section Error: Reference source not found for details)
- Configure pads (PIN muxing) as per the Interface Selected.(Refer to Device Data Sheet Document for Pin Mux Details)
- Enable the 3PSW Ethernet Subsystem Clocks. (Refer to section Error: Reference source not found for details)
- Configure the PRCM Registers CM_ETHERNET_CLKSTCTRL, CM_ALWON_ETHERNET_0_CLKCTRL to enable power and clocks to 3PSW Ethernet Subsystem. (Refer to **PRCM** Document for register details)
- Apply Soft Reset to 3psw Subsytem,cpsw_3g, cpgmac_sl1/2 and cpdma(Refer to Soft Reset Registers in Section 4,5,6)
- Initialize the HDPs (Header Description Pointer) and CPs (Completion Pointer) to NULL
- Configure the Interrupts (Refer to section.**Interrupts**)
- Configure the CPSW_3G Control register.
- Configure the Statistics Port Enable register
- Configure the ALE. (Refer to section)
- Configure the MDIO (Refer to section **MDIO Software Interface**)
- Configure the CPDMA receive DMA controller(Refer to section Error: Reference source not found)
- Configure the CPDMA transmit DMA controller.(Refer to section Error: Reference source not found)
- Configure the CPPI Tx and Rx Descriptors(Refer to section Transmit Operation and Receive Operation)
- Configure CPGMAC_SL1 and CPGMAC_SL2 as per the desired mode of operations.
- Start up RX and TX DMA (Write to HDP of Rx and Tx).

Table 13-32. PORTCTL3 Register Field Descriptions

Bit	Field	Type	Reset	Description
31-24	BCAST_LIMIT	R/W	0h	Broadcast Packet Rate Limit - Each prescale pulse loads this field into the port broadcast rate limit counter. The port counters are decremented with each packet received or transmitted depending on whether the mode is transmit or receive. If the counters decrement to zero, then further packets are rate limited until the next prescale pulse. Broadcast rate limiting is enabled by a non-zero value in this field
23-16	MCAST_LIMIT	R/W	0h	Multicast Packet Rate Limit - Each prescale pulse loads this field into the port multicast rate limit counter. The port counters are decremented with each packet received or transmitted depending on whether the mode is transmit or receive. If the counters decrement to zero, then further packets are rate limited until the next prescale pulse. Multicast rate limiting is enabled by a non-zero value in this field.
5	NO_SA_UPDATE	R/W	0h	No Souce Address Update - When set the port is disabled from updating the source port number in an ALE table entry.
4	NO_LEARN	R/W	0h	No Learn Mode - When set the port is disabled from learning an address.
3	VID_INGRESS_CHECK	R/W	0h	VLAN ID Ingress Check - If VLAN not found then drop the packet. Packets with an unknown (default) VLAN will be dropped.
2	DROP_UNTAGGED	R/W	0h	Drop Untagged Packets - Drop non-VLAN tagged ingress packets.
1-0	PORT_STATE	R/W	0h	Port State 0 - Disabled 1 - Blocked 2 - Learn 3 - Forward

LEGEND: R/W = Read/Write; R = Read only; W1toCl = Write 1 to clear bit; -*n* = value after reset

Table 13-33. CONTROL Register Field Descriptions

Bit	Field	Type	Reset	Description
31	ENABLE_ALE	R/W	0h	Enable ALE - 0 - Drop all packets 1 - Enable ALE packet processing
30	CLEAR_TABLE	R/W	0h	Clear ALE address table - Setting this bit causes the ALE hardware to write all table bit values to zero. Software must perform a clear table operation as part of the ALE setup/configuration process. Setting this bit causes all ALE accesses to be held up for 64 clocks while the clear is performed. Access to all ALE registers will be blocked (wait states) until the 64 clocks have completed. This bit cannot be read as one because the read is blocked until the clear table is completed at which time this bit is cleared to zero.
29	AGE_OUT_NOW	R/W	0h	Age Out Address Table Now - Setting this bit causes the ALE hardware to remove (free up) any ageable table entry that does not have a set touch bit. This bit is cleared when the age out process has completed. This bit may be read. The age out process takes 4096 clocks best case (no ale packet processing during ageout) and 66550 clocks absolute worst case.
8	EN_P0_UNI_FLOOD	R/W	0h	Enable Port 0 (Host Port) unicast flood 0 - do not flood unknown unicast packets to host port (p0) 1 - flood unknown unicast packets to host port (p0)
7	LEARN_NO_VID	R/W	0h	Learn No VID - 0 - VID is learned with the source address 1 - VID is not learned with the source address (source address is not tied to VID).
6	EN_VID0_MODE	R/W	0h	Enable VLAN ID = 0 Mode 0 - Process the packet with VID = PORT_VLAN[11:0]. 1 - Process the packet with VID = 0.
5	ENABLE_OUI_DENY	R/W	0h	Enable OUI Deny Mode - When set this bit indicates that a packet with a non OUI table entry matching source address will be dropped to the host unless the destination address matches a multicast table entry with the super bit set.
4	BYPASS	R/W	0h	ALE Bypass - When set, all packets received on ports 0 and 1 are sent to the host (only to the host).

Table 13-33. CONTROL Register Field Descriptions (continued)

Bit	Field	Type	Reset	Description
3	RATE_LIMIT_TX	R/W	0h	Rate Limit Transmit mode - 0 - Broadcast and multicast rate limit counters are received port based 1 - Broadcast and multicast rate limit counters are transmit port based.
2	VLAN_AWARE	R/W	0h	ALE VLAN Aware - Determines what is done if VLAN not found. 0 - Flood if VLAN not found 1 - Drop packet if VLAN not found
1	ENABLE_AUTH_MODE	R/W	0h	Enable MAC Authorization Mode - Mac authorization mode requires that all table entries be made by the host software. There are no learned address in authorization mode and the packet will be dropped if the source address is not found (and the destination address is not a multicast address with the super table entry bit set). 0 - The ALE is not in MAC authorization mode 1 - The ALE is in MAC authorization mode
0	ENABLE_RATE_LIMIT	R/W	0h	Enable Broadcast and Multicast Rate Limit 0 - Broadcast/Multicast rates not limited 1 - Broadcast/Multicast packet reception limited to the port control register rate limit fields.

Table 13-99. RX4_CP Register Field Descriptions

Bit	Field	Type	Reset	Description
31-0	RX_CP	R/W	0h	Rx Completion Pointer Register - This register is written by the host with the buffer descriptor address for the last buffer processed by the host during interrupt processing. The port uses the value written to determine if the interrupt should be deasserted. Note: The value read is the completion pointer (interrupt acknowledge) value that was written by the CPDMA DMA controller (port). The value written to this register by the host is compared with the value that the port wrote to determine if the interrupt should remain asserted. The value written is not actually stored in the location. The interrupt is deasserted if the two values are equal.

																															R/W-0h

LEGEND: R/W = Read/Write; R = Read only; W1toCl = Write 1 to clear bit; *-n* = value after reset

Table 13-103. CPDMA_SOFT_RESET Register Field Descriptions

Bit	Field	Type	Reset	Description
0	SOFT_RESET	R/W	0h	Software reset - Writing a one to this bit causes the CPDMA logic to be reset. Software reset occurs when the RX and TX DMA Controllers are in an idle state to avoid locking up the VBUSP bus. After writing a one to this bit, it may be polled to determine if the reset has occurred. If a one is read, the reset has not yet occurred. If a zero is read then reset has occurred.

LEGEND: R/W = Read/Write; R = Read only; W1toCl = Write 1 to clear bit; -*n* = value after reset

Table 13-104. DMACONTROL Register Field Descriptions

Bit	Field	Type	Reset	Description
15-8	TX_RLIM	R/W	0h	Transmit Rate Limit Channel Bus 00000000 - no rate-limited channels 10000000 - channel 7 is rate-limited 11000000 - channels 7 downto 6 are rate-limited 11100000 - channels 7 downto 5 are rate-limited 11110000 - channels 7 downto 4 are rate-limited 11111000 - channels 7 downto 3 are rate-limited 11111100 - channels 7 downto 2 are rate-limited 11111110 - channels 7 downto 1 are rate-limited 11111111 - channels 7 downto 0 are rate-limited all others invalid - this bus must be set msb towards lsb. tx_ptype must be set if any tx_rlim bit is set for fixed priority.
4	RX_CEF	R/W	0h	RX Copy Error Frames Enable - Enables DMA overrun frames to be transferred to memory (up to the point of overrun). The overrun error bit will be set in the frame EOP buffer descriptor. Overrun frame data will be filtered when rx_cef is not set. Frames coming from the receive FIFO with other error bits set are not effected by this bit. 0 - Frames containing overrun errors are filtered. 1 - Frames containing overrun errors are transferred to memory.
3	CMD_IDLE	R/W	0h	Command Idle 0 - Idle not commanded 1 - Idle Commanded (read idle in DMAStatus)
2	RX_OFFLEN_BLOCK	R/W	0h	Receive Offset/Length word write block. 0 - Do not block the DMA writes to the receive buffer descriptor offset/buffer length word. The offset/buffer length word is written as specified in CPPI 3.0. 1 - Block all CPDMA DMA controller writes to the receive buffer descriptor offset/buffer length words during CPPI packet processing. when this bit is set, the CPDMA will never write the third word to any receive buffer descriptor.
1	RX_OWNERSHIP	R/W	0h	Receive Ownership Write Bit Value. 0 - The CPDMA writes the receive ownership bit to zero at the end of packet processing as specified in CPPI 3.0. 1 - The CPDMA writes the receive ownership bit to one at the end of packet processing. Users who do not use the ownership mechanism can use this mode to preclude the necessity of software having to set this bit each time the buffer descriptor is used.

LEGEND: R/W = Read/Write; R = Read only; W1toCl = Write 1 to clear bit; -*n* = value after reset

Table 13-107. RX_BUFFER_OFFSET Register Field Descriptions

Bit	Field	Type	Reset	Description
15-0	RX_BUFFER_OFFSET	R/W	0h	Receive Buffer Offset Value - The rx_buffer_offset will be written by the port into each frame SOP buffer descriptor buffer_offset field. The frame data will begin after the rx_buffer_offset value of bytes. A value of 0x0000 indicates that there are no unused bytes at the beginning of the data and that valid data begins on the first byte of the buffer. A value of 0x000F (decimal 15) indicates that the first 15 bytes of the buffer are to be ignored by the port and that valid buffer data starts on byte 16 of the buffer. This value is used for all channels.

13.7.2 CPTS_TS_PUSH Register (offset = h + (Ch)) [reset = 0h]

TIME STAMP EVENT PUSH REGISTER

CPTS_TS_PUSH is shown in Figure 13-111 and described in Table 13-120.

Figure 13-111. CPTS_TS_PUSH Register

31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
Reserved																															TS_PUSH
																															W-0h

LEGEND: R/W = Read/Write; R = Read only; W1toCl = Write 1 to clear bit; *-n* = value after reset

Table 13-120. CPTS_TS_PUSH Register Field Descriptions

Bit	Field	Type	Reset	Description
0	TS_PUSH	W	0h	Time stamp event push - When a logic high is written to this bit a time stamp event is pushed onto the event FIFO. The time stamp value is the time of the write of this register, not the time of the event read. The time stamp value can then be read on interrupt via the event registers. Software should not push a second time stamp event onto the event FIFO until the first time stamp value has been read from the event FIFO (there should be only one time stamp event in the event FIFO at any given time). This bit is write only and always reads zero.

LEGEND: R/W = Read/Write; R = Read only; W1toCl = Write 1 to clear bit; *-n* = value after reset

Table 13-121. CPTS_TS_LOAD_VAL Register Field Descriptions

Bit	Field	Type	Reset	Description
31-0	TS_LOAD_VAL	R/W	0h	Time Stamp Load Value - Writing the ts_load_en bit causes the value contained in this register to be written into the time stamp. The time stamp value is read by initiating a time stamp push event, not by reading this register. When reading this register, the value read is not the time stamp, but is the value that was last written to this register.

LEGEND: R/W = Read/Write; R = Read only; W1toCl = Write 1 to clear bit; *-n* = value after reset

Table 13-138. P1_MAX_BLKS Register Field Descriptions

Bit	Field	Type	Reset	Description
8-4	P1_TX_MAX_BLKS	R/W	11h	Transmit FIFO Maximum Blocks - This value is the maximum number of 1k memory blocks that may be allocated to the FIFO's logical transmit priority queues. 0x11 is the recommended value of p1_tx_max_blks unless the port is in fullduplex flow control mode. In flow control mode, the p1_rx_max_blks will need to increase in order to accept the required run out in fullduplex mode. This value will need to decrease by the amount of increase in p1_rx_max_blks. 0xe is the minimum value tx max blks.
3-0	P1_RX_MAX_BLKS	R/W	3h	Receive FIFO Maximum Blocks - This value is the maximum number of 1k memory blocks that may be allocated to the FIFO's logical receive queue. This value must be greater than or equal to 0x3. It should be increased In fullduplex flow control mode to 0x5 or 0x6 depending on the required runout space. The p1_tx_max_blks value must be decreased by the amount of increase in p1_rx_max_blks. 0x3 is the minimum value rx max blks and 0x6 is the maximum value.

Table 13-147. P1_SEND_PERCENT Register Field Descriptions

Bit	Field	Type	Reset	Description
22-16	PRI3_SEND_PERCENT	R/W	0h	Priority 3 Transmit Percentage - This percentage value is sent from FIFO priority 3 (maximum) when the p1_pri3_shape_en is set (queue shaping enabled). This is the percentage of the wire that packets from priority 3 receive (which includes interpacket gap and preamble bytes). If shaping is enabled on this queue then this value must be between zero and 0d100 (not inclusive).
14-8	PRI2_SEND_PERCENT	R/W	0h	Priority 2 Transmit Percentage - This percentage value is sent from FIFO priority 2 (maximum) when the p1_pri2_shape_en is set (queue shaping enabled). This is the percentage of the wire that packets from priority 2 receive (which includes interpacket gap and preamble bytes). If shaping is enabled on this queue then this value must be between zero and 0d100 (not inclusive).
6-0	PRI1_SEND_PERCENT	R/W	0h	Priority 1 Transmit Percentage - This percentage value is sent from FIFO priority 1 (maximum) when the p1_pri1_shape_en is set (queue shaping enabled). This is the percentage of the wire that packets from priority 1 receive (which includes interpacket gap and preamble bytes). If shaping is enabled on this queue then this value must be between zero and 0d100 (not inclusive).

LEGEND: R/W = Read/Write; R = Read only; W1toCl = Write 1 to clear bit; *-n* = value after reset

Table 13-160. P2_MAX_BLKS Register Field Descriptions

Bit	Field	Type	Reset	Description
8-4	P2_TX_MAX_BLKS	R/W	11h	Transmit FIFO Maximum Blocks - This value is the maximum number of 1k memory blocks that may be allocated to the FIFO's logical transmit priority queues. 0x11 is the recommended value of p2_tx_max_blks unless the port is in fullduplex flow control mode. In flow control mode, the p2_rx_max_blks will need to increase in order to accept the required run out in fullduplex mode. This value will need to decrease by the amount of increase in p2_rx_max_blks. 0xe is the minimum value tx max blks.
3-0	P2_RX_MAX_BLKS	R/W	3h	Receive FIFO Maximum Blocks - This value is the maximum number of 1k memory blocks that may be allocated to the FIFO's logical receive queue. This value must be greater than or equal to 0x3. It should be increased In fullduplex flow control mode to 0x5 or 0x6 depending on the required runout space. The p2_tx_max_blks value must be decreased by the amount of increase in p2_rx_max_blks. 0x3 is the minimum value rx max blks and 0x6 is the maximum value.

Table 13-168. P2_SEND_PERCENT Register Field Descriptions

Bit	Field	Type	Reset	Description
22-16	PRI3_SEND_PERCENT	R/W	0h	Priority 3 Transmit Percentage - This percentage value is sent from FIFO priority 3 (maximum) when the p1_pri3_shape_en is set (queue shaping enabled). This is the percentage of the wire that packets from priority 3 receive (which includes interpacket gap and preamble bytes). If shaping is enabled on this queue then this value must be between zero and 0d100 (not inclusive).
14-8	PRI2_SEND_PERCENT	R/W	0h	Priority 2 Transmit Percentage - This percentage value is sent from FIFO priority 2 (maximum) when the p1_pri2_shape_en is set (queue shaping enabled). This is the percentage of the wire that packets from priority 2 receive (which includes interpacket gap and preamble bytes). If shaping is enabled on this queue then this value must be between zero and 0d100 (not inclusive).
6-0	PRI1_SEND_PERCENT	R/W	0h	Priority 1 Transmit Percentage - This percentage value is sent from FIFO priority 1 (maximum) when the p1_pri1_shape_en is set (queue shaping enabled). This is the percentage of the wire that packets from priority 1 receive (which includes interpacket gap and preamble bytes). If shaping is enabled on this queue then this value must be between zero and 0d100 (not inclusive).

TX_BACKOFF							
R-0h							

LEGEND: R/W = Read/Write; R = Read only; W1toCl = Write 1 to clear bit; -*n* = value after reset

Table 13-188. BOFFTEST Register Field Descriptions

Bit	Field	Type	Reset	Description
30-26	PACEVAL	R/W	0h	Pacing Register Current Value. A non-zero value in this field indicates that transmit pacing is active. A transmit frame collision or deferral causes paceval to loaded with decimal 31, good frame transmissions (with no collisions or deferrals) cause paceval to be decremented down to zero. When paceval is nonzero, the transmitter delays 4 IPGs between new frame transmissions after each successfully transmitted frame that had no deferrals or collisions. Transmit pacing helps reduce "capture" effects improving overall network bandwidth.
25-16	RNDNUM	R/W	0h	Backoff Random Number Generator - This field allows the Backoff Random Number Generator to be read (or written in test mode only). This field can be written only when mtest has previously been set. Reading this field returns the generator's current value. The value is reset to zero and begins counting on the clock after the deassertion of reset.
15-12	COLL_COUNT	R	0h	Collision Count - The number of collisions the current frame has experienced.
9-0	TX_BACKOFF	R	0h	Backoff Count - This field allows the current value of the backoff counter to be observed for test purposes. This field is loaded automatically according to the backoff algorithm, and is decremented by one for each slot time after the collision.

LEGEND: R/W = Read/Write; R = Read only; W1toCl = Write 1 to clear bit; *-n* = value after reset

Table 13-193. MACCONTROL Register Field Descriptions

Bit	Field	Type	Reset	Description
24	RX_CMF_EN	R/W	0h	RX Copy MAC Control Frames Enable - Enables MAC control frames to be transferred to memory. MAC control frames are normally acted upon (if enabled), but not copied to memory. MAC control frames that are pause frames will be acted upon if enabled in the MacControl register, regardless of the value of rx_cmf_en. Frames transferred to memory due to rx_cmf_en will have the control bit set in their EOP buffer descriptor. 0 - MAC control frames are filtered (but acted upon if enabled). 1 - MAC control frames are transferred to memory.
23	RX_CSF_EN	R/W	0h	RX Copy Short Frames Enable - Enables frames or fragments shorter than 64 bytes to be copied to memory. Frames transferred to memory due to rx_csf_en will have the fragment or undersized bit set in their receive footer. Fragments are short frames that contain CRC/align/code errors and undersized are short frames without errors. 0 - Short frames are filtered 1 - Short frames are transferred to memory.
22	RX_CEF_EN	R/W	0h	RX Copy Error Frames Enable - Enables frames containing errors to be transferred to memory. The appropriate error bit will be set in the frame receive footer. Frames containing errors will be filtered when rx_cef _en is not set. 0 - Frames containing errors are filtered. 1 - Frames containing errors are transferred to memory.
21	TX_SHORT_GAP_LIM_EN	R/W	0h	Transmit Short Gap Limit Enable When set this bit limits the number of short gap packets transmitted to 100ppm. Each time a short gap packet is sent, a counter is loaded with 10,000 and decremented on each wireside clock. Another short gap packet will not be sent out until the counter decrements to zero. This mode is included to preclude the host from filling up the FIFO and sending every packet out with short gap which would violate the maximum number of packets per second allowed.
18	EXT_EN	R/W	0h	Control Enable - Enables the fullduplex and gigabit mode to be selected from the FULLDUPLEX_IN and GIG_IN input signals and not from the fullduplex and gig bits in this register. The FULLDUPLEX_MODE bit reflects the actual fullduplex mode selected.

Table 13-193. MACCONTROL Register Field Descriptions (continued)

Bit	Field	Type	Reset	Description
17	GIG_FORCE	R/W	0h	Gigabit Mode Force - This bit is used to force the CPGMAC_SL into gigabit mode if the input GMII_MTCLK has been stopped by the PHY.
16	IFCTL_B	R/W	0h	Interface Control B - Intended as a general purpose output bit to be used to control external gaskets associated with the GMII (GMII to RGMII etc).
15	IFCTL_A	R/W	0h	Interface Control A - Intended as a general purpose output bit to be used to control external gaskets associated with the GMII (GMII to RGMII etc).
11	CMD_IDLE	R/W	0h	Command Idle 0 - Idle not commanded 1 - Idle Commanded (read idle in MacStatus)
10	TX_SHORT_GAP_EN	R/W	0h	Transmit Short Gap Enable 0 - Transmit with a short IPG is disabled 1 - Transmit with a short IPG (when TX_SHORT_GAP input is asserted) is enabled.
7	GIG	R/W	0h	Gigabit Mode - 0 - 10/100 mode 1 - Gigabit mode (full duplex only) The GIG_OUT output is the value of this bit.
6	TX_PACE	R/W	0h	Transmit Pacing Enable 0 - Transmit Pacing Disabled 1 - Transmit Pacing Enabled
5	GMII_EN	R/W	0h	GMII Enable - 0 - GMII RX and TX held in reset. 1 - GMII RX and TX released from reset.
4	TX_FLOW_EN	R/W	0h	Transmit Flow Control Enable - Determines if incoming pause frames are acted upon in full-duplex mode. Incoming pause frames are not acted upon in half-duplex mode regardless of this bit setting. The RX_MBP_Enable bits determine whether or not received pause frames are transferred to memory. 0 - Transmit Flow Control Disabled. Full-duplex mode - Incoming pause frames are not acted upon. 1 - Transmit Flow Control Enabled . Full-duplex mode - Incoming pause frames are acted upon.
3	RX_FLOW_EN	R/W	0h	Receive Flow Control Enable - 0 - Receive Flow Control Disabled Half-duplex mode - No flow control generated collisions are sent. Full-duplex mode - No outgoing pause frames are sent. 1 - Receive Flow Control Enabled Half-duplex mode - Collisions are initiated when receive flow control is triggered. Full-duplex mode - Outgoing pause frames are sent when receive flow control is triggered.
2	MTEST	R/W	0h	Manufacturing Test mode - This bit must be set to allow writes to the Backoff_Test and PauseTimer registers.
1	LOOPBACK	R/W	0h	Loop Back Mode - Loopback mode forces internal fullduplex mode regardless of whether the fullduplex bit is set or not. The loopback bit should be changed only when GMII_en is deasserted. 0 - Not looped back 1 - Loop Back Mode enabled
0	FULLDUPLEX	R/W	0h	Full Duplex mode - Gigabit mode forces fullduplex mode regardless of whether the fullduplex bit is set or not. The FULLDUPLEX_OUT output is the value of this register bit 0 - half duplex mode 1 - full duplex mode

Table 13-209. SOFT_RESET Register Field Descriptions

Bit	Field	Type	Reset	Description
0	SOFT_RESET	R/W	0h	Software reset - Writing a one to this bit causes the 3G logic to be reset. After writing a one to this bit, it may be polled to determine if the reset has occurred. If a one is read, the reset has not yet occurred. If a zero is read then reset has occurred.

13.11 CPSW_WR Registers

Table 13-210 lists the memory-mapped registers for the CPSW_WR. See your device-specific data manual for the memory address of these registers. All other register offset addresses not listed in Table 13-210 should be considered as reserved locations and the register contents should not be modified.

Table 13-210. CPSW_WR REGISTERS

Offset	Acronym	Register Description	Section
0h	IDVER	SUBSYSTEM ID VERSION REGISTER	Section 13.11.1
64h	C2_RX_STAT	SUBSYSTEM CORE 2 RECEIVE MASKED INTERRUPT STATUS REGISTER	Section 13.11.2

14.1 Pulse-Width Modulation Subsystem (PWMSS)

14.1.1 Introduction

14.1.1.1 Features

The general features of the PWMSS are:

eHRPWM

- Dedicated 16 bit time-base with Period / Frequency control
- Can support 2 independent PWM outputs with Single edge operation
- Can support 2 independent PWM outputs with Dual edge symmetric operation
- Can support 1 independent PWM output with Dual edge asymmetric operation
- Supports Dead-band generation with independent Rising and Falling edge delay control
- Provides asynchronous over-ride control of PWM signals during fault conditions
- Supports “trip zone” allocation of both latched and un-latched fault conditions
- Allows events to trigger both CPU interrupts and start of ADC conversions
- Support PWM chopping by high frequency carrier signal, used for pulse transformer gate drives.
- High-resolution module with programmable delay line.
  - Programmable on a per PWM period basis.
  - Can be inserted either on the rising edge or falling edge of the PWM pulse or both or not at all.

eCAP

- Dedicated input Capture pin
- 32 bit Time Base (counter)
- 4 x 32 bit Time-stamp Capture registers (CAP1-CAP4)
- 4 stage sequencer (Mod4 counter) which is synchronized to external events (ECAPx pin edges)
- Independent Edge polarity (Rising / Falling edge) selection for all 4 events
- Input Capture signal pre-scaling (from 1 to 16)
- One-shot compare register (2 bits) to freeze captures after 1 to 4 Time-stamp events
- Control for continuous Time-stamp captures using a 4 deep circular buffer (CAP1-CAP4) scheme
- Interrupt capabilities on any of the 4 capture events

eQEP

- Input Synchronization
- Three Stage/Six Stage Digital Noise Filter
- Quadrature Decoder Unit
- Position Counter and Control unit for position measurement
- Quadrature Edge Capture unit for low speed measurement
- Unit Time base for speed/frequency measurement
- Watchdog Timer for detecting stalls

14.1.1.2 UnsupportedFeatures

The PWMSS module features not supported are shown in Table 14-1.

Table 14-1. Unsupported Features

Feature	Reason
ePWM inputs	Not pinned out
ePWM tripzone 1-5 inputs	Only Tripzone0 is pinned out
ePWM digital comparators	Inputs not connected

14.1.2 Integration

The Pulse Width Modulation Subsystem (PWMSS) includes a single instance of the Enhanced High Resolution Pulse Width Modulator (eHRPWM), Enhanced Capture (eCAP), and Enhanced Quadrature Encoded Pulse (eQEP) modules. This includes three instantiations of the PWMSS.

Figure 14-1. PWMSS Integration

14.1.2.1 PWMSS Connectivity Attributes

The general connectivity attributes for the PWMSS module are shown in Table 14-2.

Table 14-2. PWMSS Connectivity Attributes

Attributes	Type
Power Domain	Peripheral Domain
Clock Domain	PD_PER_L4LS_GCLK
Reset Signals	PER_DOM_RST_N
Idle/Wakeup Signals	Smart Idle
Interrupt Requests	2 ePWM Interrupts epwm_intr_intr - Event interrupt epwm_tz_intr – Tripzone interrupt 1 eCAP interrupt ecap_intr – Capture/PWM event interrupt 1 eQEP Interrupt eqep_intr_intr – Event interrupt All interrupts go to MPU Subsystem and PRUSS, except eQEP1 and eQEP2 interrupts (MPU Subsystem only)
DMA Requests	None
Physical Address	L4 Peripheral slave port

14.1.2.2 PWMSS Clock and Reset Management

The PWMSS controllers have separate bus interface and functional clocks.

Table 14-3. PWMSS Clock Signals

Clock Signal	Max Freq	Reference / Source	Comments
PWMSS_ocp_clk Interface / Functional clock	100 MHz	CORE_CLKOUTM4 / 2	pd_per_l4ls_gclk from PRCM

14.1.2.3 PWMSS Pin list

The external signals for the PWMSS module are shown in the following table.

Table 14-4. PWMSS Pin List

Pin	Type*	Description
EPWMxA	O	PWM output A
EPWMxB	O	PWM output B
EPWM_SYNCIN	I	PWM Sync input
EPWM_SYNCOUT	O	PWM Sync output
EPWM_TRIPZONE[5:0]	I	PWM Tripzone inputs

14.2 Enhanced High-Resolution PWM (eHRPWM) Module

14.2.1 Introduction

An effective PWM peripheral must be able to generate complex pulse width waveforms with minimal CPU overhead or intervention. It needs to be highly programmable and very flexible while being easy to understand and use. The ePWM unit described here addresses these requirements by allocating all needed timing and control resources on a per PWM channel basis. Cross coupling or sharing of resources has been avoided; instead, the ePWM is built up from smaller single channel modules with separate resources and that can operate together as required to form a system. This modular approach results in an orthogonal architecture and provides a more transparent view of the peripheral structure, helping users to understand its operation quickly.

In this chapter, the letter x within a signal or module name is used to indicate a generic ePWM instance on a device. For example, output signals EPWMxA and EPWMxB refer to the output signals from the ePWMx instance. Thus, EPWM1A and EPWM1B belong to ePWM1 and, likewise, EPWM4A and EPWM4B belong to ePWM4.

14.2.1.1 Submodule Overview

The ePWM module represents one complete PWM channel composed of two PWM outputs: EPWMxA and EPWMxB. Multiple ePWM modules are instanced within a device as shown in Figure 14-2. Each ePWM instance is identical with one exception. Some instances include a hardware extension that allows more precise control of the PWM outputs. This extension is the high-resolution pulse width modulator (HRPWM) and is described in Section 14.2.2.10. See your device-specific data manual to determine which ePWM instances include this feature. Each ePWM module is indicated by a numerical value starting with 1. For example ePWM1 is the first instance and ePWM3 is the 3rd instance in the system and ePWMx indicates any instance.

The ePWM modules are chained together via a clock synchronization scheme that allows them to operate as a single system when required. Additionally, this synchronization scheme can be extended to the capture peripheral modules (eCAP). The number of modules is device-dependent and based on target application needs. Modules can also operate stand-alone.

Each ePWM module supports the following features:

- Dedicated 16-bit time-base counter with period and frequency control
- Two PWM outputs (EPWMxA and EPWMxB) that can be used in the following configurations::
  - Two independent PWM outputs with single-edge operation
  - Two independent PWM outputs with dual-edge symmetric operation
  - One independent PWM output with dual-edge asymmetric operation
- Asynchronous override control of PWM signals through software.
- Programmable phase-control support for lag or lead operation relative to other ePWM modules.
- Hardware-locked (synchronized) phase relationship on a cycle-by-cycle basis.
- Dead-band generation with independent rising and falling edge delay control.
- Programmable trip zone allocation of both cycle-by-cycle trip and one-shot trip on fault conditions.
- A trip condition can force either high, low, or high-impedance state logic levels at PWM outputs.
- Programmable event prescaling minimizes CPU overhead on interrupts.
- PWM chopping by high-frequency carrier signal, useful for pulse transformer gate drives.

Each ePWM module is connected to the input/output signals shown in Figure 14-2. The signals are described in detail in subsequent sections.

The order in which the ePWM modules are connected may differ from what is shown in Figure 14-2. See Section 14.2.2.3.3.2 for the synchronization scheme for a particular device. Each ePWM module consists of seven submodules and is connected within a system via the signals shown in Figure 14-3.

Figure 14-3. Submodules and Signal Connections for an ePWM Module

Figure 14-4 shows more internal details of a single ePWM module. The main signals used by the ePWM module are:

- **PWM output signals (EPWMxA and EPWMxB).** The PWM output signals are made available external to the device through the GPIO peripheral described in the system control and interrupts guide for your device.
- **Trip-zone signals ($\overline{TZ1}$ to $\overline{TZn}$).** These input signals alert the ePWM module of an external fault condition. Each module on a device can be configured to either use or ignore any of the trip-zone signals. The trip-zone signal can be configured as an asynchronous input through the GPIO peripheral. See your device-specific data manual to determine how many trip-zone pins are available in the device.
- **Time-base synchronization input (EPWMxSYNCI) and output (EPWMxSYNCO) signals.** The synchronization signals daisy chain the ePWM modules together. Each module can be configured to either use or ignore its synchronization input. The clock synchronization input and output signal are brought out to pins only for ePWM1 (ePWM module #1). The synchronization output for ePWM1 (EPWM1SYNCO) is also connected to the SYNCI of the first enhanced capture module (eCAP1).
- **Peripheral Bus.** The peripheral bus is 32-bits wide and allows both 16-bit and 32-bit writes to the ePWM register file.

Figure 14-4 also shows the key internal submodule interconnect signals. Each submodule is described in detail in .

14.2.1.2 Register Mapping

Table 14-5 shows the complete ePWM module control and status register set grouped by submodule. Each register set is duplicated for each instance of the ePWM module. The start address for each ePWM register file instance on a device is specified in the appropriate data manual.

Table 14-5. ePWM Module Control and Status Registers Grouped by Submodule

Acronym	Offset [1]	Size (×16)	Shadow	Register Description
Time-Base Submodule Registers				
TBCTL	0h	1	No	Time-Base Control Register
TBSTS	2h	1	No	Time-Base Status Register
TBPHSHR	4h	1	No	Extension for HRPWM Phase Register [2]
TBPHS	6h	1	No	Time-Base Phase Register
TBCNT	8h	1	No	Time-Base Counter Register
TBPRD	Ah	1	Yes	Time-Base Period Register
Counter-Compare Submodule Registers				
CMPCTL	Eh	1	No	Counter-Compare Control Register
CMPAHR	10h	1	No	Extension for HRPWM Counter-Compare A Register [2]
CMPA	12h	1	Yes	Counter-Compare A Register
CMPB	14h	1	Yes	Counter-Compare B Register
Action-Qualifier Submodule Registers				
AQCTLA	16h	1	No	Action-Qualifier Control Register for Output A (EPWMxA)
AQCTLB	18h	1	No	Action-Qualifier Control Register for Output B (EPWMxB)
AQSFRC	1Ah	1	No	Action-Qualifier Software Force Register
AQCSFRC	1Ch	1	Yes	Action-Qualifier Continuous S/W Force Register Set
Dead-Band Generator Submodule Registers				
DBCTL	1Eh	1	No	Dead-Band Generator Control Register
DBRED	20h	1	No	Dead-Band Generator Rising Edge Delay Count Register
DBFED	22h	1	No	Dead-Band Generator Falling Edge Delay Count Register
PWM-Chopper Submodule Registers				
PCCTL	3Ch	1	No	PWM-Chopper Control Register
Trip-Zone Submodule Registers				
TZSEL	24h	1	No	Trip-Zone Select Register
TZCTL	28h	1	No	Trip-Zone Control Register
TZEINT	2Ah	1	No	Trip-Zone Enable Interrupt Register
TZFLG	2Ch	1	No	Trip-Zone Flag Register
TZCLR	2Eh	1	No	Trip-Zone Clear Register
TZFRC	30h	1	No	Trip-Zone Force Register
Event-Trigger Submodule Registers				
ETSEL	32h	1	No	Event-Trigger Selection Register
ETPS	34h	1	No	Event-Trigger Pre-Scale Register
ETFLG	36h	1	No	Event-Trigger Flag Register
ETCLR	38h	1	No	Event-Trigger Clear Register
ETFRC	3Ah	1	No	Event-Trigger Force Register
High-Resolution PWM (HRPWM) Submodule Registers				
HRCNFG	1040h	1	No	HRPWM Configuration Register [2]

(1) Locations not shown are reserved.

(2) These registers are only available on ePWM instances that include the high-resolution PWM (HRPWM) extension; otherwise, these locations are reserved. See your device-specific data manual to determine which instances include the HRPWM.

14.2.2 Functional Description

Seven submodules are included in every ePWM peripheral. There are some instances that include a high-resolution submodule that allows more precise control of the PWM outputs. Each of these submodules performs specific tasks that can be configured by software.

14.2.2.1 Overview

Table 14-6 lists the eight key submodules together with a list of their main configuration parameters. For example, if you need to adjust or control the duty cycle of a PWM waveform, then you should see the counter-compare submodule in Section 14.2.2.4 for relevant details.

Table 14-6. Submodule Configuration Parameters

Submodule	Configuration Parameter or Option
Time-base (TB)	• Scale the time-base clock (TBCLK) relative to the system clock (SYSCLKOUT). • Configure the PWM time-base counter (TBCNT) frequency or period. • Set the mode for the time-base counter: – count-up mode: used for asymmetric PWM – count-down mode: used for asymmetric PWM – count-up-and-down mode: used for symmetric PWM • Configure the time-base phase relative to another ePWM module. • Synchronize the time-base counter between modules through hardware or software. • Configure the direction (up or down) of the time-base counter after a synchronization event. • Configure how the time-base counter will behave when the device is halted by an emulator. • Specify the source for the synchronization output of the ePWM module: – Synchronization input signal – Time-base counter equal to zero – Time-base counter equal to counter-compare B (CMPB) – No output synchronization signal generated.
Counter-compare (CC)	• Specify the PWM duty cycle for output EPWMxA and/or output EPWMxB • Specify the time at which switching events occur on the EPWMxA or EPWMxB output
Action-qualifier (AQ)	• Specify the type of action taken when a time-base or counter-compare submodule event occurs: – No action taken – Output EPWMxA and/or EPWMxB switched high – Output EPWMxA and/or EPWMxB switched low – Output EPWMxA and/or EPWMxB toggled • Force the PWM output state through software control • Configure and control the PWM dead-band through software
Dead-band (DB)	• Control of traditional complementary dead-band relationship between upper and lower switches • Specify the output rising-edge-delay value • Specify the output falling-edge delay value • Bypass the dead-band module entirely. In this case the PWM waveform is passed through without modification.
PWM-chopper (PC)	• Create a chopping (carrier) frequency. • Pulse width of the first pulse in the chopped pulse train. • Duty cycle of the second and subsequent pulses. • Bypass the PWM-chopper module entirely. In this case the PWM waveform is passed through without modification.

Table 14-6. Submodule Configuration Parameters (continued)

Submodule	Configuration Parameter or Option
Trip-zone (TZ)	• Configure the ePWM module to react to one, all, or none of the trip-zone pins. • Specify the tripping action taken when a fault occurs: – Force EPWMxA and/or EPWMxB high – Force EPWMxA and/or EPWMxB low – Force EPWMxA and/or EPWMxB to a high-impedance state – Configure EPWMxA and/or EPWMxB to ignore any trip condition. • Configure how often the ePWM will react to each trip-zone pin: – One-shot – Cycle-by-cycle • Enable the trip-zone to initiate an interrupt. • Bypass the trip-zone module entirely.
Event-trigger (ET)	• Enable the ePWM events that will trigger an interrupt. • Specify the rate at which events cause triggers (every occurrence or every second or third occurrence) • Poll, set, or clear event flags
High-Resolution PWM (HRPWM)	• Enable extended time resolution capabilities • Configure finer time granularity control or edge positioning

Code examples are provided in the remainder of this chapter that show how to implement various ePWM module configurations. These examples use the constant definitions shown in Example 14-1.

14.2.2.2 Proper Interrupt Initialization Procedure

When the ePWM peripheral clock is enabled it may be possible that interrupt flags may be set due to spurious events due to the ePWM registers not being properly initialized. The proper procedure for initializing the ePWM peripheral is:

1. Disable global interrupts (CPU INTM flag)
2. Disable ePWM interrupts
3. Initialize peripheral registers
4. Clear any spurious ePWM flags
5. Enable ePWM interrupts
6. Enable global interrupts

14.2.2.3 Time-Base (TB) Submodule

Each ePWM module has its own time-base submodule that determines all of the event timing for the ePWM module. Built-in synchronization logic allows the time-base of multiple ePWM modules to work together as a single system. Figure 14-5 illustrates the time-base module's place within the ePWM.

Figure 14-5. Time-Base Submodule Block Diagram

14.2.2.3.1 Purpose of the Time-Base Submodule

You can configure the time-base submodule for the following:

- Specify the ePWM time-base counter (TBCNT) frequency or period to control how often events occur.
- Manage time-base synchronization with other ePWM modules.
- Maintain a phase relationship with other ePWM modules.
- Set the time-base counter to count-up, count-down, or count-up-and-down mode.
- Generate the following events:
  - CTR = PRD: Time-base counter equal to the specified period (TBCNT = TBPRD) .
  - CTR = 0: Time-base counter equal to zero (TBCNT = 0000h).
- Configure the rate of the time-base clock; a prescaled version of the CPU system clock (SYSCLKOUT). This allows the time-base counter to increment/decrement at a slower rate.

14.2.2.3.2 Controlling and Monitoring the Time-Base Submodule

Table 14-7 lists the registers used to control and monitor the time-base submodule.

Table 14-7. Time-Base Submodule Registers

Acronym	Register Description	Address Offset	Shadowed
TBCTL	Time-Base Control Register	0h	No
TBSTS	Time-Base Status Register	2h	No
TBPHSHR	HRPWM extension Phase Register [(1)]	4h	No
TBPHS	Time-Base Phase Register	6h	No
TBCNT	Time-Base Counter Register	8h	No
TBPRD	Time-Base Period Register	Ah	Yes

(1) This register is available only on ePWM instances that include the high-resolution extension (HRPWM). On ePWM modules that do not include the HRPWM, this location is reserved. See your device-specific data manual to determine which ePWM instances include this feature.

Figure 14-6 shows the critical signals and registers of the time-base submodule. Table 14-8 provides descriptions of the key signals associated with the time-base submodule.

Figure 14-6. Time-Base Submodule Signals and Registers

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Table 14-8. Key Time-Base Signals

Signal	Description
EPWMxSYNCI	Time-base synchronization input. Input pulse used to synchronize the time-base counter with the counter of ePWM module earlier in the synchronization chain. An ePWM peripheral can be configured to use or ignore this signal. For the first ePWM module (EPWM1) this signal comes from a device pin. For subsequent ePWM modules this signal is passed from another ePWM peripheral. For example, EPWM2SYNCI is generated by the ePWM1 peripheral, EPWM3SYNCI is generated by ePWM2 and so forth. See Section 14.2.2.3.3.2 for information on the synchronization order of a particular device.
EPWMxSYNCO	Time-base synchronization output. This output pulse is used to synchronize the counter of an ePWM module later in the synchronization chain. The ePWM module generates this signal from one of three event sources: 1. EPWMxSYNCI (Synchronization input pulse) 2. CTR = 0: The time-base counter equal to zero (TBCNT = 0000h). 3. CTR = CMPB: The time-base counter equal to the counter-compare B (TBCNT = CMPB) register.
CTR = PRD	Time-base counter equal to the specified period. This signal is generated whenever the counter value is equal to the active period register value. That is when TBCNT = TBPRD.
CTR = 0	Time-base counter equal to zero. This signal is generated whenever the counter value is zero. That is when TBCNT equals 0000h.
CTR = CMPB	Time-base counter equal to active counter-compare B register (TBCNT = CMPB). This event is generated by the counter-compare submodule and used by the synchronization out logic.
CTR_dir	Time-base counter direction. Indicates the current direction of the ePWM's time-base counter. This signal is high when the counter is increasing and low when it is decreasing.
CTR_max	Time-base counter equal max value. (TBCNT = FFFFh) Generated event when the TBCNT value reaches its maximum value. This signal is only used only as a status bit.
TBCLK	Time-base clock. This is a prescaled version of the system clock (SYSCLKOUT) and is used by all submodules within the ePWM. This clock determines the rate at which time-base counter increments or decrements.

14.2.2.3.3 Calculating PWM Period and Frequency

The frequency of PWM events is controlled by the time-base period (TBPRD) register and the mode of the time-base counter. Figure 14-7 shows the period (T_{pwm}) and frequency (F_{pwm}) relationships for the up-count, down-count, and up-down-count time-base counter modes when when the period is set to 4 (TBPRD = 4). The time increment for each step is defined by the time-base clock (TBCLK) which is a prescaled version of the system clock (SYSCLKOUT).

The time-base counter has three modes of operation selected by the time-base control register (TBCTL):

- **Up-Down-Count Mode:** In up-down-count mode, the time-base counter starts from zero and increments until the period (TBPRD) value is reached. When the period value is reached, the time-base counter then decrements until it reaches zero. At this point the counter repeats the pattern and begins to increment.
- **Up-Count Mode:** In this mode, the time-base counter starts from zero and increments until it reaches the value in the period register (TBPRD). When the period value is reached, the time-base counter resets to zero and begins to increment once again.
- **Down-Count Mode:** In down-count mode, the time-base counter starts from the period (TBPRD) value and decrements until it reaches zero. When it reaches zero, the time-base counter is reset to the period value and it begins to decrement once again.

Copyright © 2011, Texas Instruments Incorporated

Figure 14-7. Time-Base Frequency and Period

14.2.2.3.3.1 Time-Base Period Shadow Register

The time-base period register (TBPRD) has a shadow register. Shadowing allows the register update to be synchronized with the hardware. The following definitions are used to describe all shadow registers in the ePWM module:

- **Active Register:** The active register controls the hardware and is responsible for actions that the hardware causes or invokes.
- **Shadow Register:** The shadow register buffers or provides a temporary holding location for the active register. It has no direct effect on any control hardware. At a strategic point in time the shadow register's content is transferred to the active register. This prevents corruption or spurious operation due to the register being asynchronously modified by software.

The memory address of the shadow period register is the same as the active register. Which register is written to or read from is determined by the TBCTL[PRDLD] bit. This bit enables and disables the TBPRD shadow register as follows:

- **Time-Base Period Shadow Mode:** The TBPRD shadow register is enabled when TBCTL[PRDLD] = 0. Reads from and writes to the TBPRD memory address go to the shadow register. The shadow register contents are transferred to the active register (TBPRD (Active) ← TBPRD (shadow)) when the time-base counter equals zero (TBCNT = 0000h). By default the TBPRD shadow register is enabled.
- **Time-Base Period Immediate Load Mode:** If immediate load mode is selected (TBCTL[PRDLD] = 1), then a read from or a write to the TBPRD memory address goes directly to the active register.

14.2.2.3.3.2 Time-Base Counter Synchronization

A time-base synchronization scheme connects all of the ePWM modules on a device. Each ePWM module has a synchronization input (EPWMxSYNCI) and a synchronization output (EPWMxSYNCO). The input synchronization for the first instance (ePWM1) comes from an external pin. The possible synchronization connections for the remaining ePWM modules is shown in Figure 14-8.

Figure 14-8. Time-Base Counter Synchronization Scheme 1

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Each ePWM module can be configured to use or ignore the synchronization input. If the TBCTL[PHSEN] bit is set, then the time-base counter (TBCNT) of the ePWM module will be automatically loaded with the phase register (TBPHS) contents when one of the following conditions occur:

- **EPWMxSYNCI: Synchronization Input Pulse:** The value of the phase register is loaded into the counter register when an input synchronization pulse is detected (TBPHS → TBCNT). This operation occurs on the next valid time-base clock (TBCLK) edge.
- **Software Forced Synchronization Pulse:** Writing a 1 to the TBCTL[SWFSYNC] control bit invokes a software forced synchronization. This pulse is ORed with the synchronization input signal, and therefore has the same effect as a pulse on EPWMxSYNCI.

This feature enables the ePWM module to be automatically synchronized to the time base of another ePWM module. Lead or lag phase control can be added to the waveforms generated by different ePWM modules to synchronize them. In up-down-count mode, the TBCTL[PSHDIR] bit configures the direction of the time-base counter immediately after a synchronization event. The new direction is independent of the direction prior to the synchronization event. The TBPHS bit is ignored in count-up or count-down modes. See Figure 14-9 through Figure 14-12 for examples.

Clearing the TBCTL[PHSEN] bit configures the ePWM to ignore the synchronization input pulse. The synchronization pulse can still be allowed to flow-through to the EPWMxSYNCO and be used to synchronize other ePWM modules. In this way, you can set up a master time-base (for example, ePWM1) and downstream modules (ePWM2 - ePWMx) may elect to run in synchronization with the master.

14.2.2.3.4 Phase Locking the Time-Base Clocks of Multiple ePWM Modules

The TBCLKSYNC bit in the chip configuration register 1 (CFGCHIP1) in the System Module can be used to globally synchronize the time-base clocks of all enabled ePWM modules on a device. The TBCLKSYNC bit is part of the chip configuration registers and is described in the device-specific data manual. When TBCLKSYNC = 0, the time-base clock of all ePWM modules is stopped (default). When TBCLKSYNC = 1, all ePWM time-base clocks are started with the rising edge of TBCLK aligned. For perfectly synchronized TBCLKs, the prescaler bits in the TBCTL register of each ePWM module must be set identically. The proper procedure for enabling the ePWM clocks is as follows:

1. Enable the ePWM module clocks.
2. Set TBCLKSYNC = 0. This will stop the time-base clock within any enabled ePWM module.
3. Configure the prescaler values and desired ePWM modes.
4. Set TBCLKSYNC = 1.

14.2.2.3.5 Time-Base Counter Modes and Timing Waveforms

The time-base counter operates in one of four modes:

- Up-count mode which is asymmetrical.
- Down-count mode which is asymmetrical.
- Up-down-count which is symmetrical.
- Frozen where the time-base counter is held constant at the current value.

To illustrate the operation of the first three modes, Figure 14-9 to Figure 14-12 show when events are generated and how the time-base responds to an EPWMxSYNCI signal.

14.2.2.4.1 Purpose of the Counter-Compare Submodule

The counter-compare submodule takes as input the time-base counter value. This value is continuously compared to the counter-compare A (CMPA) and counter-compare B (CMPB) registers. When the time-base counter is equal to one of the compare registers, the counter-compare unit generates an appropriate event.

The counter-compare submodule:

- Generates events based on programmable time stamps using the CMPA and CMPB registers
  - CTR = CMPA: Time-base counter equals counter-compare A register (TBCNT = CMPA).
  - CTR = CMPB: Time-base counter equals counter-compare B register (TBCNT = CMPB)
- Controls the PWM duty cycle if the action-qualifier submodule is configured appropriately
- Shadows new compare values to prevent corruption or glitches during the active PWM cycle

14.2.2.4.2 Controlling and Monitoring the Counter-Compare Submodule

Table 14-9 lists the registers used to control and monitor the counter-compare submodule. Table 14-10 lists the key signals associated with the counter-compare submodule.

Table 14-9. Counter-Compare Submodule Registers

Acronym	Register Description	Address Offset	Shadowed
CMPCTL	Counter-Compare Control Register.	Eh	No
CMPAHR	HRPWM Counter-Compare A Extension Register [(1)]	10h	Yes
CMPA	Counter-Compare A Register	12h	Yes
CMPB	Counter-Compare B Register	14h	Yes

(1) This register is available only on ePWM modules with the high-resolution extension (HRPWM). On ePWM modules that do not include the HRPWM, this location is reserved. Refer to the device-specific data manual to determine which ePWM instances include this feature.

Table 14-10. Counter-Compare Submodule Key Signals

Signal	Description of Event	Registers Compared
CTR = CMPA	Time-base counter equal to the active counter-compare A value	TBCNT = CMPA
CTR = CMPB	Time-base counter equal to the active counter-compare B value	TBCNT = CMPB
CTR = PRD	Time-base counter equal to the active period. Used to load active counter-compare A and B registers from the shadow register	TBCNT = TBPRD
CTR = 0	Time-base counter equal to zero. Used to load active counter-compare A and B registers from the shadow register	TBCNT = 0000h

14.2.2.4.3 Operational Highlights for the Counter-Compare Submodule

The counter-compare submodule is responsible for generating two independent compare events based on two compare registers:

1. CTR = CMPA: Time-base counter equal to counter-compare A register (TBCNT = CMPA).
2. CTR = CMPB: Time-base counter equal to counter-compare B register (TBCNT = CMPB).

For up-count or down-count mode, each event occurs only once per cycle. For up-down-count mode each event occurs twice per cycle, if the compare value is between 0000h and TBPRD; and occurs once per cycle, if the compare value is equal to 0000h or equal to TBPRD. These events are fed into the action-qualifier submodule where they are qualified by the counter direction and converted into actions if enabled. Refer to Section 14.2.2.5.1 for more details.

The counter-compare registers CMPA and CMPB each have an associated shadow register. Shadowing provides a way to keep updates to the registers synchronized with the hardware. When shadowing is used, updates to the active registers only occurs at strategic points. This prevents corruption or spurious operation due to the register being asynchronously modified by software. The memory address of the active register and the shadow register is identical. Which register is written to or read from is determined by the CMPCTL[SHDWAMODE] and CMPCTL[SHDWBMODE] bits. These bits enable and disable the CMPA shadow register and CMPB shadow register respectively. The behavior of the two load modes is described below:

- **Shadow Mode:** The shadow mode for the CMPA is enabled by clearing the CMPCTL[SHDWAMODE] bit and the shadow register for CMPB is enabled by clearing the CMPCTL[SHDWBMODE] bit. Shadow mode is enabled by default for both CMPA and CMPB.

  If the shadow register is enabled then the content of the shadow register is transferred to the active register on one of the following events:

  – CTR = PRD: Time-base counter equal to the period (TBCNT = TBPRD).
  – CTR = 0: Time-base counter equal to zero (TBCNT = 0000h)
  – Both CTR = PRD and CTR = 0

  Which of these three events is specified by the CMPCTL[LOADAMODE] and CMPCTL[LOADBMODE] register bits. Only the active register contents are used by the counter-compare submodule to generate events to be sent to the action-qualifier.
- **Immediate Load Mode:** If immediate load mode is selected (TBCTL[SHADWAMODE] = 1 or TBCTL[SHADWBMODE] = 1), then a read from or a write to the register will go directly to the active register.

14.2.2.4.4 Count Mode Timing Waveforms

The counter-compare module can generate compare events in all three count modes:

- Up-count mode: used to generate an asymmetrical PWM waveform.
- Down-count mode: used to generate an asymmetrical PWM waveform.
- Up-down-count mode: used to generate a symmetrical PWM waveform.

To best illustrate the operation of the first three modes, the timing diagrams in Figure 14-15 to Figure 14-18 show when events are generated and how the EPWMxSYNCI signal interacts.

Figure 14-15. Counter-Compare Event Waveforms in Up-Count Mode

NOTE: An EPWMxSYNCI external synchronization event can cause a discontinuity in the TBCNT count sequence. This can lead to a compare event being skipped. This skipping is considered normal operation and must be taken into account.

14.2.2.5 Action-Qualifier (AQ) Submodule

Figure 14-19 shows the action-qualifier (AQ) submodule (see shaded block) in the ePWM system. The action-qualifier submodule has the most important role in waveform construction and PWM generation. It decides which events are converted into various action types, thereby producing the required switched waveforms at the EPWMxA and EPWMxB outputs.

Figure 14-19. Action-Qualifier Submodule

14.2.2.5.1 Purpose of the Action-Qualifier Submodule

The action-qualifier submodule is responsible for the following:

- Qualifying and generating actions (set, clear, toggle) based on the following events:
  - CTR = PRD: Time-base counter equal to the period (TBCNT = TBPRD)
  - CTR = 0: Time-base counter equal to zero (TBCNT = 0000h)
  - CTR = CMPA: Time-base counter equal to the counter-compare A register (TBCNT = CMPA)
  - CTR = CMPB: Time-base counter equal to the counter-compare B register (TBCNT = CMPB)
- Managing priority when these events occur concurrently
- Providing independent control of events when the time-base counter is increasing and when it is decreasing.

14.2.2.5.2 Controlling and Monitoring the Action-Qualifier Submodule

Table 14-11 lists the registers used to control and monitor the action-qualifier submodule.

Table 14-11. Action-Qualifier Submodule Registers

Acronym	Register Description	Address Offset	Shadowed
AQCTLA	Action-Qualifier Control Register For Output A (EPWMxA)	16h	No
AQCTLB	Action-Qualifier Control Register For Output B (EPWMxB)	18h	No
AQSFRC	Action-Qualifier Software Force Register	1Ah	No
AQCSFRC	Action-Qualifier Continuous Software Force	1Ch	Yes

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

The action-qualifier submodule is based on event-driven logic. It can be thought of as a programmable cross switch with events at the input and actions at the output, all of which are software controlled via the set of registers shown in Figure 14-20. The possible input events are summarized again in Table 14-12.

Figure 14-20. Action-Qualifier Submodule Inputs and Outputs

Table 14-12. Action-Qualifier Submodule Possible Input Events

Signal	Description	Registers Compared
CTR = PRD	Time-base counter equal to the period value	TBCNT = TBPRD
CTR = 0	Time-base counter equal to zero	TBCNT = 0000h
CTR = CMPA	Time-base counter equal to the counter-compare A	TBCNT = CMPA
CTR = CMPB	Time-base counter equal to the counter-compare B	TBCNT = CMPB
Software forced event	Asynchronous event initiated by software	

The software forced action is a useful asynchronous event. This control is handled by registers AQSFRC and AQCSFRC.

The action-qualifier submodule controls how the two outputs EPWMxA and EPWMxB behave when a particular event occurs. The event inputs to the action-qualifier submodule are further qualified by the counter direction (up or down). This allows for independent action on outputs on both the count-up and count-down phases.

The possible actions imposed on outputs EPWMxA and EPWMxB are:

- **Set High:** Set output EPWMxA or EPWMxB to a high level.
- **Clear Low:** Set output EPWMxA or EPWMxB to a low level.
- **Toggle:** If EPWMxA or EPWMxB is currently pulled high, then pull the output low. If EPWMxA or EPWMxB is currently pulled low, then pull the output high.
- **Do Nothing:** Keep outputs EPWMxA and EPWMxB at same level as currently set. Although the "Do Nothing" option prevents an event from causing an action on the EPWMxA and EPWMxB outputs, this event can still trigger interrupts. See the event-trigger submodule description in Section 14.2.2.9 for details.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Actions are specified independently for either output (EPWMxA or EPWMxB). Any or all events can be configured to generate actions on a given output. For example, both CTR = CMPA and CTR = CMPB can operate on output EPWMxA. All qualifier actions are configured via the control registers found at the end of this section.

For clarity, the drawings in this chapter use a set of symbolic actions. These symbols are summarized in Figure 14-21. Each symbol represents an action as a marker in time. Some actions are fixed in time (zero and period) while the CMPA and CMPB actions are moveable and their time positions are programmed via the counter-compare A and B registers, respectively. To turn off or disable an action, use the "Do Nothing option"; it is the default at reset.

Figure 14-21. Possible Action-Qualifier Actions for EPWMxA and EPWMxB Outputs

S/W force	TB Counter equals:				Actions
	Zero	Comp A	Comp B	Period	
SW ╳	Z ╳	CA ╳	CB ╳	P ╳	Do Nothing

14.2.2.5.3 Action-Qualifier Event Priority

It is possible for the ePWM action qualifier to receive more than one event at the same time. In this case events are assigned a priority by the hardware. The general rule is events occurring later in time have a higher priority and software forced events always have the highest priority. The event priority levels for up-down-count mode are shown in Table 14-13. A priority level of 1 is the highest priority and level 7 is the lowest. The priority changes slightly depending on the direction of TBCNT.

Table 14-13. Action-Qualifier Event Priority for Up-Down-Count Mode

Priority Level	Event if TBCNT is Incrementing TBCNT = 0 up to TBCNT = TBPRD	Event if TBCNT is Decrementing TBCNT = TBPRD down to TBCNT = 1
1 (Highest)	Software forced event	Software forced event
2	Counter equals CMPB on up-count (CBU)	Counter equals CMPB on down-count (CBD)
3	Counter equals CMPA on up-count (CAU)	Counter equals CMPA on down-count (CAD)
4	Counter equals zero	Counter equals period (TBPRD)
5	Counter equals CMPB on down-count (CBD) [(1)]	Counter equals CMPB on up-count (CBU) [(1)]
6 (Lowest)	Counter equals CMPA on down-count (CAD) [(1)]	Counter equals CMPA on up-count (CBU) [(1)]

(1) To maintain symmetry for up-down-count mode, both up-events (CAU/CBU) and down-events (CAD/CBD) can be generated for TBPRD. Otherwise, up-events can occur only when the counter is incrementing and down-events can occur only when the counter is decrementing.

Table 14-14 shows the action-qualifier priority for up-count mode. In this case, the counter direction is always defined as up and thus down-count events will never be taken.

Table 14-14. Action-Qualifier Event Priority for Up-Count Mode

Priority Level	Event
1 (Highest)	Software forced event
2	Counter equal to period (TBPRD)
3	Counter equal to CMPB on up-count (CBU)
4	Counter equal to CMPA on up-count (CAU)
5 (Lowest)	Counter equal to Zero

Table 14-15 shows the action-qualifier priority for down-count mode. In this case, the counter direction is always defined as down and thus up-count events will never be taken.

Table 14-15. Action-Qualifier Event Priority for Down-Count Mode

Priority Level	Event
1 (Highest)	Software forced event
2	Counter equal to Zero
3	Counter equal to CMPB on down-count (CBD)
4	Counter equal to CMPA on down-count (CAD)
5 (Lowest)	Counter equal to period (TBPRD)

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

It is possible to set the compare value greater than the period. In this case the action will take place as shown in Table 14-16.

Table 14-16. Behavior if CMPA/CMPB is Greater than the Period

Counter Mode	Compare on Up-Count Event CAU/CBU	Compare on Down-Count Event CAU/CBU
Up-Count Mode	If CMPA/CMPB ≤ TBPRD period, then the event occurs on a compare match (TBCNT = CMPA or CMPB). If CMPA/CMPB > TBPRD, then the event will not occur.	Never occurs.
Down-Count Mode	Never occurs.	If CMPA/CMPB < TBPRD, the event will occur on a compare match (TBCNT = CMPA or CMPB). If CMPA/CMPB ≥ TBPRD, the event will occur on a period match (TBCNT = TBPRD).
Up-Down-Count Mode	If CMPA/CMPB < TBPRD and the counter is incrementing, the event occurs on a compare match (TBCNT = CMPA or CMPB). If CMPA/CMPB is ≥ TBPRD, the event will occur on a period match (TBCNT = TBPRD).	If CMPA/CMPB < TBPRD and the counter is decrementing, the event occurs on a compare match (TBCNT = CMPA or CMPB). If CMPA/CMPB ≥ TBPRD, the event occurs on a period match (TBCNT = TBPRD).

14.2.2.5.4 Waveforms for Common Configurations

NOTE: The waveforms in this chapter show the ePWMs behavior for a static compare register value. In a running system, the active compare registers (CMPA and CMPB) are typically updated from their respective shadow registers once every period. The user specifies when the update will take place; either when the time-base counter reaches zero or when the time-base counter reaches period. There are some cases when the action based on the new value can be delayed by one period or the action based on the old value can take effect for an extra period. Some PWM configurations avoid this situation. These include, but are not limited to, the following:

Use up-down-count mode to generate a symmetric PWM:

- If you load CMPA/CMPB on zero, then use CMPA/CMPB values greater than or equal to 1.
- If you load CMPA/CMPB on period, then use CMPA/CMPB values less than or equal to TBPRD - 1.

  This means there will always be a pulse of at least one TBCLK cycle in a PWM period which, when very short, tend to be ignored by the system.

Use up-down-count mode to generate an asymmetric PWM:

- To achieve 50%-0% asymmetric PWM use the following configuration: Load CMPA/CMPB on period and use the period action to clear the PWM and a compare-up action to set the PWM. Modulate the compare value from 0 to TBPRD to achieve 50%-0% PWM duty.

When using up-count mode to generate an asymmetric PWM:

- To achieve 0-100% asymmetric PWM use the following configuration: Load CMPA/CMPB on TBPRD. Use the Zero action to set the PWM and a compare-up action to clear the PWM. Modulate the compare value from 0 to TBPRD+1 to achieve 0-100% PWM duty.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Figure 14-22 shows how a symmetric PWM waveform can be generated using the up-down-count mode of the TBCNT. In this mode 0%-100% DC modulation is achieved by using equal compare matches on the up count and down count portions of the waveform. In the example shown, CMPA is used to make the comparison. When the counter is incrementing the CMPA match will pull the PWM output high. Likewise, when the counter is decrementing the compare match will pull the PWM signal low. When CMPA = 0, the PWM signal is low for the entire period giving the 0% duty waveform. When CMPA = TBPRD, the PWM signal is high achieving 100% duty.

When using this configuration in practice, if you load CMPA/CMPB on zero, then use CMPA/CMPB values greater than or equal to 1. If you load CMPA/CMPB on period, then use CMPA/CMPB values less than or equal to TBPRD-1. This means there will always be a pulse of at least one TBCLK cycle in a PWM period which, when very short, tend to be ignored by the system.

Figure 14-22. Up-Down-Count Mode Symmetrical Waveform

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

The PWM waveforms in Figure 14-23 through Figure 14-28 show some common action-qualifier configurations. Some conventions used in the figures are as follows:

- TBPRD, CMPA, and CMPB refer to the value written in their respective registers. The active register, not the shadow register, is used by the hardware.
- CMPx, refers to either CMPA or CMPB.
- EPWMxA and EPWMxB refer to the output signals from ePWMx
- Up-Down means Count-up-and-down mode, Up means up-count mode and Dwn means down-count mode
- Sym = Symmetric, Asym = Asymmetric

Table 14-17 and Table 14-18 contains initialization and runtime register configurations for the waveforms in Figure 14-23.

Figure 14-23. Up, Single Edge Asymmetric Waveform, With Independent Modulation on EPWMxA and EPWMxB—Active High

(1) PWM period = (TBPRD + 1) × T_{TBCLK}

(2) Duty modulation for EPWMxA is set by CMPA, and is active high (that is, high time duty proportional to CMPA).

(3) Duty modulation for EPWMxB is set by CMPB and is active high (that is, high time duty proportional to CMPB).

(4) The "Do Nothing" actions (X) are shown for completeness, but will not be shown on subsequent diagrams.

(5) Actions at zero and period, although appearing to occur concurrently, are actually separated by one TBCLK period. TBCNT wraps from period to 0000h.

14.2.2.6 Dead-Band Generator (DB) Submodule

Figure 14-29 illustrates the dead-band generator submodule within the ePWM module.

Figure 14-29. Dead-Band Generator Submodule

14.2.2.6.1 Purpose of the Dead-Band Submodule

The "Action-qualifier (AQ) Module" section discussed how it is possible to generate the required dead-band by having full control over edge placement using both the CMPA and CMPB resources of the ePWM module. However, if the more classical edge delay-based dead-band with polarity control is required, then the dead-band generator submodule should be used.

The key functions of the dead-band generator submodule are:

- Generating appropriate signal pairs (EPWMxA and EPWMxB) with dead-band relationship from a single EPWMxA input
- Programming signal pairs for:
  - Active high (AH)
  - Active low (AL)
  - Active high complementary (AHC)
  - Active low complementary (ALC)
- Adding programmable delay to rising edges (RED)
- Adding programmable delay to falling edges (FED)
- Can be totally bypassed from the signal path (note dotted lines in diagram)

14.2.2.6.2 Controlling and Monitoring the Dead-Band Submodule

The dead-band generator submodule operation is controlled and monitored via the following registers:

Table 14-29. Dead-Band Generator Submodule Registers

Acronym	Register Description	Address Offset	Shadowed
DBCTL	Dead-Band Control Register	1Eh	No
DBRED	Dead-Band Rising Edge Delay Count Register	20h	No
DBFED	Dead-Band Falling Edge Delay Count Register	22h	No

Copyright © 2011, Texas Instruments Incorporated

14.2.2.6.3 Operational Highlights for the Dead-Band Generator Submodule

The following sections provide the operational highlights.

The dead-band submodule has two groups of independent selection options as shown in Figure 14-30.

- **Input Source Selection:** The input signals to the dead-band module are the EPWMxA and EPWMxB output signals from the action-qualifier. In this section they will be referred to as EPWMxA In and EPWMxB In. Using the DBCTL[IN_MODE) control bits, the signal source for each delay, falling-edge or rising-edge, can be selected:
  - EPWMxA In is the source for both falling-edge and rising-edge delay. This is the default mode.
  - EPWMxA In is the source for falling-edge delay, EPWMxB In is the source for rising-edge delay.
  - EPWMxA In is the source for rising edge delay, EPWMxB In is the source for falling-edge delay.
  - EPWMxB In is the source for both falling-edge and rising-edge delay.
- **Output Mode Control:** The output mode is configured by way of the DBCTL[OUT_MODE] bits. These bits determine if the falling-edge delay, rising-edge delay, neither, or both are applied to the input signals.
- **Polarity Control:** The polarity control (DBCTL[POLSEL]) allows you to specify whether the rising-edge delayed signal and/or the falling-edge delayed signal is to be inverted before being sent out of the dead-band submodule.

Figure 14-30. Configuration Options for the Dead-Band Generator Submodule

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Although all combinations are supported, not all are typical usage modes. Table 14-30 lists some classical dead-band configurations. These modes assume that the DBCTL[IN_MODE] is configured such that EPWMxA In is the source for both falling-edge and rising-edge delay. Enhanced, or non-traditional modes can be achieved by changing the input signal source. The modes shown in Table 14-30 fall into the following categories:

- **Mode 1: Bypass both falling-edge delay (FED) and rising-edge delay (RED)** Allows you to fully disable the dead-band submodule from the PWM signal path.
- **Mode 2-5: Classical Dead-Band Polarity Settings** These represent typical polarity configurations that should address all the active high/low modes required by available industry power switch gate drivers. The waveforms for these typical cases are shown in Figure 14-31. Note that to generate equivalent waveforms to Figure 14-31, configure the action-qualifier submodule to generate the signal as shown for EPWMxA.
- **Mode 6: Bypass rising-edge-delay and Mode 7: Bypass falling-edge-delay** Finally the last two entries in Table 14-30 show combinations where either the falling-edge-delay (FED) or rising-edge-delay (RED) blocks are bypassed.

Table 14-30. Classical Dead-Band Operating Modes

		DBCTL[POLSEL]		DBCTL[OUT_MODE]	
Mode	**Mode Description** [(1)]	**S3**	**S2**	**S1**	**S0**
1	EPWMxA and EPWMxB Passed Through (No Delay)	x	x	0	0
2	Active High Complementary (AHC)	1	0	1	1
3	Active Low Complementary (ALC)	0	1	1	1
4	Active High (AH)	0	0	1	1
5	Active Low (AL)	1	1	1	1
6	EPWMxA Out = EPWMxA In (No Delay) EPWMxB Out = EPWMxA In with Falling Edge Delay	0 or 1	0 or 1	0	1
7	EPWMxA Out = EPWMxA In with Rising Edge Delay EPWMxB Out = EPWMxB In with No Delay	0 or 1	0 or 1	1	0

(1) These are classical dead-band modes and assume that DBCTL[IN_MODE] = 0,0. That is, EPWMxA in is the source for both the falling-edge and rising-edge delays. Enhanced, non-traditional modes can be achieved by changing the IN_MODE configuration.

Figure 14-31 shows waveforms for typical cases where 0% < duty < 100%.

Figure 14-31. Dead-Band Waveforms for Typical Cases (0% < Duty < 100%)

The dead-band submodule supports independent values for rising-edge (RED) and falling-edge (FED) delays. The amount of delay is programmed using the DBRED and DBFED registers. These are 10-bit registers and their value represents the number of time-base clock, TBCLK, periods a signal edge is delayed by. For example, the formula to calculate falling-edge-delay and rising-edge-delay are:

$FED = DBFED \times T_{TBCLK}$

$RED = DBRED \times T_{TBCLK}$

Where T_{TBCLK} is the period of TBCLK, the prescaled version of SYSCLKOUT.

14.2.2.7 PWM-Chopper (PC) Submodule

Figure 14-32 illustrates the PWM-chopper (PC) submodule within the ePWM module. The PWM-chopper submodule allows a high-frequency carrier signal to modulate the PWM waveform generated by the action-qualifier and dead-band submodules. This capability is important if you need pulse transformer-based gate drivers to control the power switching elements.

Figure 14-32. PWM-Chopper Submodule

14.2.2.7.1 Purpose of the PWM-Chopper Submodule

The key functions of the PWM-chopper submodule are:

- Programmable chopping (carrier) frequency
- Programmable pulse width of first pulse
- Programmable duty cycle of second and subsequent pulses
- Can be fully bypassed if not required

14.2.2.7.2 Controlling the PWM-Chopper Submodule

The PWM-chopper submodule operation is controlled via the register in Table 14-31.

Table 14-31. PWM-Chopper Submodule Registers

14.2.2.7.3 Operational Highlights for the PWM-Chopper Submodule

Figure 14-33 shows the operational details of the PWM-chopper submodule. The carrier clock is derived from SYSCLKOUT. Its frequency and duty cycle are controlled via the CHPFREQ and CHPDUTY bits in the PCCTL register. The one-shot block is a feature that provides a high energy first pulse to ensure hard and fast power switch turn on, while the subsequent pulses sustain pulses, ensuring the power switch remains on. The one-shot width is programmed via the OSHTWTH bits. The PWM-chopper submodule can be fully disabled (bypassed) via the CHPEN bit.

Figure 14-33. PWM-Chopper Submodule Signals and Registers

14.2.2.7.4 Waveforms

Figure 14-34 shows simplified waveforms of the chopping action only; one-shot and duty-cycle control are not shown. Details of the one-shot and duty-cycle control are discussed in the following sections.

Figure 14-34. Simple PWM-Chopper Submodule Waveforms Showing Chopping Action Only

14.2.2.7.4.1 One-Shot Pulse

The width of the first pulse can be programmed to any of 16 possible pulse width values. The width or period of the first pulse is given by:

$T_{1stpulse} = T_{SYSCLKOUT} \times 8 \times OSHTWTH$

Where $T_{SYSCLKOUT}$ is the period of the system clock (SYSCLKOUT) and OSHTWTH is the four control bits (value from 1 to 16)

Figure 14-35 shows the first and subsequent sustaining pulses.

Figure 14-35. PWM-Chopper Submodule Waveforms Showing the First Pulse and Subsequent Sustaining Pulses

14.2.2.7.4.2 Duty Cycle Control

Pulse transformer-based gate drive designs need to comprehend the magnetic properties or characteristics of the transformer and associated circuitry. Saturation is one such consideration. To assist the gate drive designer, the duty cycles of the second and subsequent pulses have been made programmable. These sustaining pulses ensure the correct drive strength and polarity is maintained on the power switch gate during the on period, and hence a programmable duty cycle allows a design to be tuned or optimized via software control.

Figure 14-36 shows the duty cycle control that is possible by programming the CHPDUTY bits. One of seven possible duty ratios can be selected ranging from 12.5% to 87.5%.

14.2.2.8 Trip-Zone (TZ) Submodule

Figure 14-37 shows how the trip-zone (TZ) submodule fits within the ePWM module. Each ePWM module is connected to every $\overline{TZ}$ signal that are sourced from the GPIO MUX. These signals indicates external fault or trip conditions, and the ePWM outputs can be programmed to respond accordingly when faults occur. See your device-specific data manual to determine the number of trip-zone pins available for the device.

Figure 14-37. Trip-Zone Submodule

14.2.2.8.1 *Purpose of the Trip-Zone Submodule*

The key functions of the trip-zone submodule are:

- Trip inputs $\overline{TZ1}$ to $\overline{TZn}$ can be flexibly mapped to any ePWM module.
- Upon a fault condition, outputs EPWMxA and EPWMxB can be forced to one of the following:
  - High
  - Low
  - High-impedance
  - No action taken
- Support for one-shot trip (OSHT) for major short circuits or over-current conditions.
- Support for cycle-by-cycle tripping (CBC) for current limiting operation.
- Each trip-zone input pin can be allocated to either one-shot or cycle-by-cycle operation.
- Interrupt generation is possible on any trip-zone pin.
- Software-forced tripping is also supported.
- The trip-zone submodule can be fully bypassed if it is not required.

14.2.2.8.2 Controlling and Monitoring the Trip-Zone Submodule

The trip-zone submodule operation is controlled and monitored through the following registers:

Table 14-32. Trip-Zone Submodule Registers

Acronym	Register Description	Address Offset	Shadowed
TZSEL	Trip-Zone Select Register	24h	No
TZCTL	Trip-Zone Control Register	28h	No
TZEINT	Trip-Zone Enable Interrupt Register	2Ah	No
TZFLG	Trip-Zone Flag Register	2Ch	No
TZCLR	Trip-Zone Clear Register	2Eh	No
TZFRC	Trip-Zone Force Register	30h	No

14.2.2.8.3 Operational Highlights for the Trip-Zone Submodule

The following sections describe the operational highlights and configuration options for the trip-zone submodule.

The trip-zone signals at pin $\overline{TZ1}$ to $\overline{TZn}$ is an active-low input signal. When the pin goes low, it indicates that a trip event has occurred. Each ePWM module can be individually configured to ignore or use each of the trip-zone pins. Which trip-zone pins are used by a particular ePWM module is determined by the TZSEL register for that specific ePWM module. The trip-zone signal may or may not be synchronized to the system clock (SYSCLKOUT). A minimum of 1 SYSCLKOUT low pulse on the $\overline{TZ}$ $\overline{n}$ inputs is sufficient to trigger a fault condition in the ePWM module. The asynchronous trip makes sure that if clocks are missing for any reason, the outputs can still be tripped by a valid event present on the $\overline{TZn}$ inputs.

The $\overline{TZ}$ $\overline{n}$ input can be individually configured to provide either a cycle-by-cycle or one-shot trip event for a ePWM module. The configuration is determined by the TZSEL[CBCn] and TZSEL[OSHTn] bits (where n corresponds to the trip pin) respectively.

- **Cycle-by-Cycle (CBC):** When a cycle-by-cycle trip event occurs, the action specified in the TZCTL register is carried out immediately on the EPWMxA and/or EPWMxB output. Table 14-33 lists the possible actions. In addition, the cycle-by-cycle trip event flag (TZFLG[CBC]) is set and a EPWMxTZINT interrupt is generated if it is enabled in the TZEINT register.

  The specified condition on the pins is automatically cleared when the ePWM time-base counter reaches zero (TBCNT = 0000h) if the trip event is no longer present. Therefore, in this mode, the trip event is cleared or reset every PWM cycle. The TZFLG[CBC] flag bit will remain set until it is manually cleared by writing to the TZCLR[CBC] bit. If the cycle-by-cycle trip event is still present when the TZFLG[CBC] bit is cleared, then it will again be immediately set.
- **One-Shot (OSHT):** When a one-shot trip event occurs, the action specified in the TZCTL register is carried out immediately on the EPWMxA and/or EPWMxB output. Table 14-33 lists the possible actions. In addition, the one-shot trip event flag (TZFLG[OST]) is set and a EPWMxTZINT interrupt is generated if it is enabled in the TZEINT register. The one-shot trip condition must be cleared manually by writing to the TZCLR[OST] bit.

The action taken when a trip event occurs can be configured individually for each of the ePWM output pins by way of the TZCTL[TZA] and TZCTL[TZB] register bits. One of four possible actions, shown in Table 14-33, can be taken on a trip event.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Table 14-33. Possible Actions On a Trip Event

TZCTL[TZA] and/or TZCTL[TZB]	EPWMxA and/or EPWMxB	Comment
0	High-Impedance	Tripped
1h	Force to High State	Tripped
2h	Force to Low State	Tripped
3h	No Change	Do Nothing. No change is made to the output.

Example 14-2. Trip-Zone Configurations

Scenario A:
A one-shot trip event on $\overline{TZ1}$ pulls both EPWM1A, EPWM1B low and also forces EPWM2A and EPWM2B high.

- Configure the ePWM1 registers as follows:
  - TZSEL[OSHT1] = 1: enables $\overline{TZ}$ as a one-shot event source for ePWM1
  - TZCTL[TZA] = 2: EPWM1A will be forced low on a trip event.
  - TZCTL[TZB] = 2: EPWM1B will be forced low on a trip event.
- Configure the ePWM2 registers as follows:
  - TZSEL[OSHT1] = 1: enables $\overline{TZ}$ as a one-shot event source for ePWM2
  - TZCTL[TZA] = 1: EPWM2A will be forced high on a trip event.
  - TZCTL[TZB] = 1: EPWM2B will be forced high on a trip event.

Scenario B:
A cycle-by-cycle event on $\overline{TZ5}$ pulls both EPWM1A, EPWM1B low.

A one-shot event on $\overline{TZ1}$ or $\overline{TZ6}$ puts EPWM2A into a high impedance state.

- Configure the ePWM1 registers as follows:
  - TZSEL[CBC5] = 1: enables $\overline{TZ5}$ as a one-shot event source for ePWM1
  - TZCTL[TZA] = 2: EPWM1A will be forced low on a trip event.
  - TZCTL[TZB] = 2: EPWM1B will be forced low on a trip event.
- Configure the ePWM2 registers as follows:
  - TZSEL[OSHT1] = 1: enables $\overline{TZ1}$ as a one-shot event source for ePWM2
  - TZSEL[OSHT6] = 1: enables $\overline{TZ6}$ as a one-shot event source for ePWM1
  - TZCTL[TZA] = 0: EPWM1A will be put into a high-impedance state on a trip event.
  - TZCTL[TZB] = 3: EPWM1B will ignore the trip event.

14.2.2.8.4 Generating Trip Event Interrupts

Figure 14-38 and Figure 14-39 illustrate the trip-zone submodule control and interrupt logic, respectively.

14.2.2.9 Event-Trigger (ET) Submodule

Figure 14-40 shows the event-trigger (ET) submodule in the ePWM system. The event-trigger submodule manages the events generated by the time-base submodule and the counter-compare submodule to generate an interrupt to the CPU.

Figure 14-40. Event-Trigger Submodule

14.2.2.9.1 *Purpose of the Event-Trigger Submodule*

The key functions of the event-trigger submodule are:

- Receives event inputs generated by the time-base and counter-compare submodules
- Uses the time-base direction information for up/down event qualification
- Uses prescaling logic to issue interrupt requests at:
  - Every event
  - Every second event
  - Every third event
- Provides full visibility of event generation via event counters and flags

14.2.2.9.2 *Controlling and Monitoring the Event-Trigger Submodule*

The key registers used to configure the event-trigger submodule are shown in Table 14-34:

Table 14-34. Event-Trigger Submodule Registers

Acronym	Register Description	Address Offset	Shadowed
ETSEL	Event-Trigger Selection Register	32h	No
ETPS	Event-Trigger Prescale Register	34h	No
ETFLG	Event-Trigger Flag Register	36h	No
ETCLR	Event-Trigger Clear Register	38h	No
ETFRC	Event-Trigger Force Register	3Ah	No

14.2.2.9.3 Operational Overview of the Event-Trigger Submodule

The following sections describe the event-trigger submodule's operational highlights.

Each ePWM module has one interrupt request line connected to the interrupt controller as shown in Figure 14-41.

Figure 14-41. Event-Trigger Submodule Inter-Connectivity to Interrupt Controller

The event-trigger submodule monitors various event conditions (the left side inputs to event-trigger submodule shown in Figure 14-42) and can be configured to prescale these events before issuing an Interrupt request. The event-trigger prescaling logic can issue Interrupt requests at:

- Every event
- Every second event
- Every third event

Figure 14-42. Event-Trigger Submodule Showing Event Inputs and Prescaled Outputs

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

- ETSEL—This selects which of the possible events will trigger an interrupt.
- ETPS—This programs the event prescaling options previously mentioned.
- ETFLG—These are flag bits indicating status of the selected and prescaled events.
- ETCLR—These bits allow you to clear the flag bits in the ETFLG register via software.
- ETFRC—These bits allow software forcing of an event. Useful for debugging or software intervention.

A more detailed look at how the various register bits interact with the Interrupt is shown in Figure 14-43.

Figure 14-43 shows the event-trigger's interrupt generation logic. The interrupt-period (ETPS[INTPRD]) bits specify the number of events required to cause an interrupt pulse to be generated. The choices available are:

- Do not generate an interrupt
- Generate an interrupt on every event
- Generate an interrupt on every second event
- Generate an interrupt on every third event

An interrupt cannot be generated on every fourth or more events.

Which event can cause an interrupt is configured by the interrupt selection (ETSEL[INTSEL]) bits. The event can be one of the following:

- Time-base counter equal to zero (TBCNT = 0000h).
- Time-base counter equal to period (TBCNT = TBPRD).
- Time-base counter equal to the compare A register (CMPA) when the timer is incrementing.
- Time-base counter equal to the compare A register (CMPA) when the timer is decrementing.
- Time-base counter equal to the compare B register (CMPB) when the timer is incrementing.
- Time-base counter equal to the compare B register (CMPB) when the timer is decrementing.

The number of events that have occurred can be read from the interrupt event counter (ETPS[INTCNT]) register bits. That is, when the specified event occurs the ETPS[INTCNT] bits are incremented until they reach the value specified by ETPS[INTPRD]. When ETPS[INTCNT] = ETPS[INTPRD] the counter stops counting and its output is set. The counter is only cleared when an interrupt is sent to the interrupt controller.

When ETPS[INTCNT] reaches ETPS[INTPRD], one of the following behaviors will occur:

- If interrupts are enabled, ETSEL[INTEN] = 1 and the interrupt flag is clear, ETFLG[INT] = 0, then an interrupt pulse is generated and the interrupt flag is set, ETFLG[INT] = 1, and the event counter is cleared ETPS[INTCNT] = 0. The counter will begin counting events again.
- If interrupts are disabled, ETSEL[INTEN] = 0, or the interrupt flag is set, ETFLG[INT] = 1, the counter stops counting events when it reaches the period value ETPS[INTCNT] = ETPS[INTPRD].
- If interrupts are enabled, but the interrupt flag is already set, then the counter will hold its output high until the ENTFLG[INT] flag is cleared. This allows for one interrupt to be pending while one is serviced.

Writing to the INTPRD bits will automatically clear the counter INTCNT = 0 and the counter output will be reset (so no interrupts are generated). Writing a 1 to the ETFRC[INT] bit will increment the event counter INTCNT. The counter will behave as described above when INTCNT = INTPRD. When INTPRD = 0, the counter is disabled and hence no events will be detected and the ETFRC[INT] bit is also ignored.

14.2.2.10 High-Resolution PWM (HRPWM) Submodule

Figure 14-44 shows the high-resolution PWM (HRPWM) submodule in the ePWM system. Some devices include the high-resolution PWM submodule, see your device-specific data manual to determine which ePWM instances include this feature.

Figure 14-44. HRPWM System Interface

Copyright © 2011, Texas Instruments Incorporated

14.2.2.10.1 Purpose of the High-Resolution PWM Submodule

The enhanced high-resolution pulse-width modulator (eHRPWM) extends the time resolution capabilities of the conventionally derived digital pulse-width modulator (PWM). HRPWM is typically used when PWM resolution falls below ~9-10 bits. The key features of HRPWM are:

- Extended time resolution capability
- Used in both duty cycle and phase-shift control methods
- Finer time granularity control or edge positioning using extensions to the Compare A and Phase registers
- Implemented using the A signal path of PWM, that is, on the EPWMxA output. EPWMxB output has conventional PWM capabilities

The ePWM peripheral is used to perform a function that is mathematically equivalent to a digital-to-analog converter (DAC). As shown in Figure 14-45, the effective resolution for conventionally generated PWM is a function of PWM frequency (or period) and system clock frequency.

Figure 14-45. Resolution Calculations for Conventionally Generated PWM

If the required PWM operating frequency does not offer sufficient resolution in PWM mode, you may want to consider HRPWM. As an example of improved performance offered by HRPWM, Table 14-35 shows resolution in bits for various PWM frequencies. Table 14-35 values assume a MEP step size of 180 ps. See your device-specific data manual for typical and maximum performance specifications for the MEP.

Table 14-35. Resolution for PWM and HRPWM

	Regular Resolution (PWM)		High Resolution (HRPWM)	
PWM Frequency (kHz)	Bits	%	Bits	%
20	12.3	0.0	18.1	0.000
50	11.0	0.0	16.8	0.001
100	10.0	0.1	15.8	0.002
150	9.4	0.2	15.2	0.003
200	9.0	0.2	14.8	0.004
250	8.6	0.3	14.4	0.005
500	7.6	0.5	13.8	0.007
1000	6.6	1.0	12.4	0.018
1500	6.1	1.5	11.9	0.027
2000	5.6	2.0	11.4	0.036

Although each application may differ, typical low-frequency PWM operation (below 250 kHz) may not require HRPWM. HRPWM capability is most useful for high-frequency PWM requirements of power conversion topologies such as:

- Single-phase buck, boost, and flyback
- Multi-phase buck, boost, and flyback
- Phase-shifted full bridge
- Direct modulation of D-Class power amplifiers

14.2.2.10.2 Architecture of the High-Resolution PWM Submodule

The HRPWM is based on micro edge positioner (MEP) technology. MEP logic is capable of positioning an edge very finely by sub-dividing one coarse system clock of a conventional PWM generator. The time step accuracy is on the order of 150 ps. The HRPWM also has a self-check software diagnostics mode to check if the MEP logic is running optimally, under all operating conditions.

Figure 14-46 shows the relationship between one coarse system clock and edge position in terms of MEP steps, which are controlled via an 8-bit field in the Compare A extension register (CMPAHR).

Figure 14-46. Operating Logic Using MEP

Number of coarse steps = integer(PWMduty * PWMperiod)
Number of MEP steps = fraction(PWMduty * PWMperiod) * (MEPScaleFactor)

16−bit CMPA register value	= number of coarse steps
16−bit CMPAHR register value	= (number of MEP steps) << 8 + 0x180 (rounding) (A)

A For MEP range and rounding adjustment.

To generate an HRPWM waveform, configure the TBM, CCM, and AQM registers as you would to generate a conventional PWM of a given frequency and polarity. The HRPWM works together with the TBM, CCM, and AQM registers to extend edge resolution, and should be configured accordingly. Although many programming combinations are possible, only a few are needed and practical.

14.2.2.10.3 Controlling and Monitoring the High-Resolution PWM Submodule

The MEP of the HRPWM is controlled by two extension registers, each 8-bits wide. These two HRPWM registers are concatenated with the 16-bit TBPHS and CMPA registers used to control PWM operation.

- TBPHSHR - Time-Base Phase High-Resolution Register
- CMPAHR - Counter-Compare A High-Resolution Register

Table 14-36 lists the registers used to control and monitor the high-resolution PWM submodule.

Table 14-36. HRPWM Submodule Registers

Acronym	Register Description	Address Offset	Shadowed
TBPHSHR	Extension Register for HRPWM Phase	4h	No
CMPAHR	Extension Register for HRPWM Duty	10h	Yes
HRCNFG	HRPWM Configuration Register	1040h	No

14.2.2.10.4 Configuring the High-Resolution PWM Submodule

Once the ePWM has been configured to provide conventional PWM of a given frequency and polarity, the HRPWM is configured by programming the HRCNFG register located at offset address 1040h. This register provides configuration options for the following key operating modes:

- **Edge Mode:** The MEP can be programmed to provide precise position control on the rising edge (RE), falling edge (FE), or both edges (BE) at the same time. FE and RE are used for power topologies requiring duty cycle control, while BE is used for topologies requiring phase shifting, for example, phase shifted full bridge.
- **Control Mode:** The MEP is programmed to be controlled either from the CMPAHR register (duty cycle control) or the TBPHSHR register (phase control). RE or FE control mode should be used with CMPAHR register. BE control mode should be used with TBPHSHR register.
- **Shadow Mode:** This mode provides the same shadowing (double buffering) option as in regular PWM mode. This option is valid only when operating from the CMPAHR register and should be chosen to be the same as the regular load option for the CMPA register. If TBPHSHR is used, then this option has no effect.

14.2.2.10.5 Operational Highlights for the High-Resolution PWM Submodule

The MEP logic is capable of placing an edge in one of 255 (8 bits) discrete time steps, each of which has a time resolution on the order of 150 ps. The MEP works with the TBM and CCM registers to be certain that time steps are optimally applied and that edge placement accuracy is maintained over a wide range of PWM frequencies, system clock frequencies and other operating conditions. Table 14-37 shows the typical range of operating frequencies supported by the HRPWM.

Table 14-37. Relationship Between MEP Steps, PWM Frequency and Resolution

System (MHz)	MEP Steps Per SYSCLKOUT (1) (2) (3)	PWM Minimum (Hz) (4)	PWM Maximum (MHz)	Resolution at Maximum (Bits) (5)
50.0	111	763	2.50	11.1
60.0	93	916	3.00	10.9
70.0	79	1068	3.50	10.6
80.0	69	1221	4.00	10.4
90.0	62	1373	4.50	10.3
100.0	56	1526	5.00	10.1

(1) System frequency = SYSCLKOUT, that is, CPU clock. TBCLK = SYSCLKOUT
(2) Table data based on a MEP time resolution of 180 ps (this is an example value)
(3) MEP steps applied = $T_{SYSCLKOUT}$/180 ps in this example.
(4) PWM minimum frequency is based on a maximum period value, TBPRD = 65 535. PWM mode is asymmetrical up-count.
(5) Resolution in bits is given for the maximum PWM frequency stated.

14.2.2.10.5.1 Edge Positioning

In a typical power control loop (switch modes, digital motor control (DMC), uninterruptible power supply (UPS)), a digital controller (PID, 2pole/2zero, lag/lead, etc.) issues a duty command, usually expressed in a per unit or percentage terms.

In the following example, assume that for a particular operating point, the demanded duty cycle is 0.405 or 40.5% on-time and the required converter PWM frequency is 1.25 MHz. In conventional PWM generation with a system clock of 100 MHz, the duty cycle choices are in the vicinity of 40.5%. In Figure 14-47, a compare value of 32 counts (duty = 40%) is the closest to 40.5% that you can attain. This is equivalent to an edge position of 320 ns instead of the desired 324 ns. This data is shown in Table 14-38.

By utilizing the MEP, you can achieve an edge position much closer to the desired point of 324 ns. Table 14-38 shows that in addition to the CMPA value, 22 steps of the MEP (CMPAHR register) will position the edge at 323.96 ns, resulting in almost zero error. In this example, it is assumed that the MEP has a step resolution of 180 ns.

Figure 14-47. Required PWM Waveform for a Requested Duty = 40.5%

Table 14-38. CMPA vs Duty (left), and [CMPA:CMPAHR] vs Duty (right)

CMPA (count) (1) (2) (3)	DUTY (%)	High Time (ns)	CMPA (count)	CMPAHR (count)	Duty (%)	High Time (ns)
28	35.0	280	32	18	40.405	323.24
29	36.3	290	32	19	40.428	323.42
30	37.5	300	32	20	40.450	323.60
31	38.8	310	32	21	40.473	323.78
32	40.0	320	32	22	40.495	323.96
33	41.3	330	32	23	40.518	324.14
34	42.5	340	32	24	40.540	324.32
			32	25	40.563	324.50
Required			32	26	40.585	324.68
32.40	40.5	324	32	27	40.608	324.86

(1) System clock, SYSCLKOUT and TBCLK = 100 MHz, 10 ns
(2) For a PWM Period register value of 80 counts, PWM Period = 80 × 10 ns = 800 ns, PWM frequency = 1/800 ns = 1.25 MHz
(3) Assumed MEP step size for the above example = 180 ps

14.2.2.10.5.2 Scaling Considerations

The mechanics of how to position an edge precisely in time has been demonstrated using the resources of the standard (CMPA) and MEP (CMPAHR) registers. In a practical application, however, it is necessary to seamlessly provide the CPU a mapping function from a per-unit (fractional) duty cycle to a final integer (non-fractional) representation that is written to the [CMPA:CMPAHR] register combination.

To do this, first examine the scaling or mapping steps involved. It is common in control software to express duty cycle in a per-unit or percentage basis. This has the advantage of performing all needed math calculations without concern for the final absolute duty cycle, expressed in clock counts or high time in ns. Furthermore, it makes the code more transportable across multiple converter types running different PWM frequencies.

To implement the mapping scheme, a two-step scaling procedure is required.

Assumptions for this example:

System clock, SYSCLKOUT	=	10 ns (100 MHz)
PWM frequency	=	1.25 MHz (1/800 ns)
Required PWM duty cycle, **PWMDuty**	=	0.405 (40.5%)
PWM period in terms of coarse steps, **PWMperiod** (800 ns/10 ns)	=	80
Number of MEP steps per coarse step at 180 ps (10 ns/180 ps), **MEP_SF**	=	55
Value to keep CMPAHR within the range of 1-255 and fractional rounding constant (default value)	=	180h

Step 1: Percentage Integer Duty value conversion for CMPA register

CMPA register value	=	int(**PWMDuty** × **PWMperiod**); int means integer part
	=	int(0.405 × 80)
	=	int(32.4)
CMPA register value	=	32 (20h)

Step 2: Fractional value conversion for CMPAHR register

CMPAHR register value	=	(frac(**PWMDuty** × **PWMperiod**) × **MEP_SF**) << 8) + 180h; frac means fractional part
	=	(frac(32.4) × 55 <<8) + 180h; Shift is to move the value as CMPAHR high byte
	=	((0.4 × 55) <<8) + 180h
	=	(22 <<8) + 180h
	=	22 × 256 + 180h ; Shifting left by 8 is the same multiplying by 256.
	=	5632 + 180h
	=	1600h + 180h
CMPAHR value	=	1780h; CMPAHR value = 1700h, lower 8 bits will be ignored by hardware.

14.2.2.10.5.3 Duty Cycle Range Limitation

In high resolution mode, the MEP is not active for 100% of the PWM period. It becomes operational 3 SYSCLK cycles after the period starts.

Duty cycle range limitations are illustrated in Figure 14-48. This limitation imposes a lower duty cycle limit on the MEP. For example, precision edge control is not available all the way down to 0% duty cycle. Although for the first 3 or 6 cycles, the HRPWM capabilities are not available, regular PWM duty control is still fully operational down to 0% duty. In most applications this should not be an issue as the controller regulation point is usually not designed to be close to 0% duty cycle.

Figure 14-48. Low % Duty Cycle Range Limitation Example When PWM Frequency = 1 MHz

If the application demands HRPWM operation in the low percent duty cycle region, then the HRPWM can be configured to operate in count-down mode with the rising edge position (REP) controlled by the MEP. This is illustrated in Figure 14-49. In this case low percent duty limitation is no longer an issue.

Figure 14-49. High % Duty Cycle Range Limitation Example when PWM Frequency = 1 MHz

14.2.2.10.6 Scale Factor Optimizing Software (SFO)

The micro edge positioner (MEP) logic is capable of placing an edge in one of 255 discrete time steps. As previously mentioned, the size of these steps is on the order of 150 ps. The MEP step size varies based on worst-case process parameters, operating temperature, and voltage. MEP step size increases with decreasing voltage and increasing temperature and decreases with increasing voltage and decreasing temperature. Applications that use the HRPWM feature should use the TI-supplied MEP scale factor optimizer (SFO) software functions. SFO functions help to dynamically determine the number of MEP steps per SYSCLKOUT period while the HRPWM is in operation.

To utilize the MEP capabilities effectively during the Q15 duty to [CMPA:CMPAHR] mapping function (see Section 14.2.2.10.5.2), the correct value for the MEP scaling factor (MEP_SF) needs to be known by the software. To accomplish this, each HRPWM module has built in self-check and diagnostics capabilities that can be used to determine the optimum MEP_SF value for any operating condition. TI provides a C-callable library containing two SFO functions that utilize this hardware and determine the optimum MEP_SF. As such, MEP Control and Diagnostics registers are reserved for TI use.

Currently, there are two released versions of the SFO library - SFO_TI_Build.lib and SFO_TI_Build_V5.lib. Versions 2, 3, and 4 were TI-Internal only. A high-level comparison table between the two library versions can be found in Section 14.2.2.10.6.1. A detailed description of the SFO_TI_Build.lib software functions follows in Section 14.2.2.10.6.2. Information on the SFO_TI_Build_V5.lib software functions, which support up to 16 HRPWM channels, can be found in Section 14.2.2.10.6.4.

NOTE: For floating-point devices, when compiling application code for floating point (fpu32 mode), libraries utilized by the application code must also be compiled for floating point. The SFO_TI_Build_fpu.lib and SFO_TI_Build_V5_fpu.lib are available as the floating-point compiled equivalents to the fixed-point SFO_TI_Build.lib and SFO_TI_Build_V5.lib libraries. The SFO functions in the fpu-version libraries are C-code-compatible to their fixed-point equivalents.

14.2.2.10.6.1 SFO Library Version Comparison

Table 14-39 includes a high-level comparison between SFO_TI_Build.lib and SFO_TI_Build_V5.lib. A detailed description of SFO_TI_Build_V5.lib follows the table, and more information on SFO_TI_Build.lib can be found in Section 14.2.2.10.6.

Table 14-39. SFO Library Version Comparison

	SYSCLK Frequency	ePWM Frequency	SFO_TI_Build.lib	SFO_TI_Build_V5.lib	Unit
Maximum HRPWM channels supported	-	-	Up to 4	Up to 16	channels
Total static variable memory size	-	-	220	79 (1 channel) to 192 (16 channel)	words
MepEn runs on multiple channels concurrently?	-	-	Yes	No	-
Error-checking?	-	-	No	Yes	-
Typical time required for MepEn to update MEP_ScaleFactor on 1 channel if called repetitively without interrupts	-	400 kHz	3.26	1.5	seconds
	-	1 MHz	1.308	0.6	seconds
	-	2 MHz	0.66	0.3	seconds
	-	3.33 MHz	0.396	0.18	seconds
	-	200 MHz	0.066	0.03	seconds
Typical time required for MepDis to update MEP_ScaleFactor on 1 channel if called repetitively without interrupts	100 MHz	-	0.83	1.86	milliseconds
	60 MHz	-	1.38	1.38	milliseconds
	50 MHz	-	1.66	1.66	milliseconds

14.2.2.10.6.2 SFO_TI_Build Library Routines

Table 14-40 provides functional descriptions of the two SFO library routines in SFO_TI_Build.lib.

Table 14-40. SFO Library Routines

Function	Description
SFO_MepDis(n)	**Scale Factor Optimizer with MEP Disabled** This routine runs faster, as the calibration logic works when HRPWM capabilities are disabled; therefore, HRPWM capabilities cannot be run concurrently when the ePWMn is being used. The function returns a value in the variable array: MEP_ScaleFactor[n][1] = Number of MEP steps/SYSCLKOUT If TBCLK is not equal to SYSCLKOUT, then the returned value must be adjusted to reflect the correct TBCLK: MEP steps per TBCLK = MEP_ScaleFactor[n] × (SYSCLKOUT/TBCLK)[1] **Constraints when using this function:** MEP diagnostics logic uses SYSCLKOUT not TBCLK and hence SYSCLKOUT restriction is an important constraint. SFO_MepDis(n) function does not require a starting Scale Factor value. **When to use:** If one of the ePWM modules is not used in HRPWM mode, then it can be dedicated to run the SFO diagnostics for the modules that are running HRPWM mode. Here the single MEP_SF value obtained can be applied to other ePWM modules. This assumes that all HRPWM module's MEP steps are similar but may not be identical. The ePWM module that is not active in HRPWM mode is still fully operational in conventional PWM mode and can be used to drive PWM pins. The SFO function only makes use of the MEP diagnostics logic. The other ePWM modules operating in HRPWM mode incur only a 3-cycle minimum duty limitation.
SFO_MepEn(n)	**Scale Factor Optimizer with MEP Enabled** This routine runs slower as the calibration logic is used concurrently while HRPWM capabilities are being used by the ePWM module. The function returns a value in the variable array: MEP_ScaleFactor[n][1] = Number of MEP steps/SYSCLKOUT = Number of MEP steps/TBCLK **Constraints when using this function:** MEP diagnostics logic uses SYSCLKOUT not TBCLK and hence SYSCLKOUT restriction is an important constraint. SFO_MepEn(n) function does require a starting Scale Factor value.MEP_ScaleFactor[0] needs to be initialized to a typical MEP step size value. **NOTE:** SFO_MepEn(n) only supports the following HRPWM configuration: • HRCNFG[HRLOAD] = 0 (load on CTR = 0) • HRCNFG[EDGMODE] = 10 (falling edge MEP control) **When to use:** If the application requires all ePWM modules to have HRPWM capability (MEP is operational), then the SFO_MepEn(n) function should run for each of the active ePWM modules with HRPWM capability. • In the above case, a 6-cycle MEP inactivity zone exists at the start of the PWM period. See Section 14.2.2.10.5.3 on duty cycle range limitation. • If all ePWM modules are using the same TBCLK prescaler, then it is also possible to run the SFO_MepEn(n) function for only one ePWM module and to use the SFO return value for the other modules. In this case only one ePWM module incurs the 6-cycle limitation, and remaining modules incur only a 3-cycle minimum duty limitation. See "Duty cycle limitation" section. This assumes that all HRPWM module's MEP steps are similar but may not be identical.

(1) n is the ePWM module number on which the SFO function operates.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Both routines can be run as background tasks in a slow loop requiring negligible CPU cycles. In most applications only one of these routines will be needed. However, if the application has free HRPWM resources then both the routines could be used. The repetition rate at which an SFO function needs to be executed depends on the applications operating environment. As with all digital CMOS devices temperature and supply voltage variations have an effect on MEP operation. However, in most applications these parameters vary slowly and therefore it is often sufficient to execute the SFO function once every 5 to 10 seconds or so. If more rapid variations are expected, then execution may have to be performed more frequently to match the application. Note, there is no high limit restriction on the SFO function repetition rate, hence it can execute as quickly as the background loop is capable.

While using HRPWM feature with no SFO diagnostics, HRPWM logic will not be active for the first 3 TBCLK cycles of the PWM period. While running the application in this configuration, if CMPA register value is less than 3 cycles, then its CMPAHR register must be cleared to zero. This would avoid any unexpected transitions on PWM signal.

However, if SFO diagnostic function SFO_MepEn is used in the background, then HRPWM logic will not be active for the first 6 TBCLK cycles of PWM period. While using SFO_MepEn function if CMPA register value is less than 6 cycles, then its CMPAHR register must be cleared to zero. This would avoid any unexpected transitions on PWM signal. Also note that the SFO_MepDis function cannot be used concurrently with PWM signals with HRPWM enabled.

14.2.2.10.6.3 SFO_TI_Build Software Usage

Software library functions SFO_MepEn(int n) and SFO_MepDis(int n) calculate the MEP scale factor for up to four ePWM modules. The scale factor is an integer value in the range 1–255, and represents the number of micro step edge positions available for a system clock period. The scale factor value is returned in a global array of integer values called MEP_ScaleFactor[x], where x is the maximum number of HRPWM channels for a device plus one. For example, see Table 14-41.

Table 14-41. Factor Values

Software function calls	Functional description	Updated Variable MEP_ScaleFactor[5] [(1)]
SFO_MepDis(n)		
SFO_MepDis(1);	Returns the scale factor value to array index 1	MEP_ScaleFactor[1]
SFO_MepDis(2);	Returns the scale factor value to array index 2	MEP_ScaleFactor[2]
SFO_MepDis(3);	Returns the scale factor value to array index 3	MEP_ScaleFactor[3]
SFO_MepDis(4);	Returns the scale factor value to array index 4	MEP_ScaleFactor[4]
SFO_MepEn(n)		
SFO_MepEn(1);	Returns the scale factor value to array index 1	MEP_ScaleFactor[1]
SFO_MepEn(2);	Returns the scale factor value to array index 2	MEP_ScaleFactor[2]
SFO_MepEn(3);	Returns the scale factor value to array index 3	MEP_ScaleFactor[3]
SFO_MepEn(4);	Returns the scale factor value to array index 4	MEP_ScaleFactor[4]

(1) MEP_ScaleFactor[0] variable is a starting value and used by the SFO software functions internally

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

To use the HRPWM feature of the ePWMs it is recommended that the SFO functions be used as follows. For different devices that may have fewer HRPWM channels, modifications will be required in Step 1 and Step 2.

NOTE: The following example assumes there are four ePWM instances that contain the HRPWM submodule in the device. See your device-specific data manual to determine the number of ePWM instances that contain the HRPWM submodule.

Step 1. Add Include Files

The SFO.h file needs to be included as follows. This include file is mandatory while using the SFO library function. These include files are optional if customized header files are used in the end applications.

Example 14-3. A Sample of How to Add Include Files

```
#include "SFO.h"                  // SFO lib functions (needed for HRPWM)
```

Step 2. Element Declaration

Declare a 5-element array of integer variables as follows:

Example 14-4. Declaring an Element

```
int    MEP_ScaleFactor[5] = {0,0,0,0,0};  // Scale factor values for ePWM1-4
int    MEP_SF1, MEP_SF2, MEP_SF3, MEP_SF4
volatile struct EPWM_REGS *ePWM[] = {&EPwm1Regs, &EPwm1Regs, &EPwm2Regs, &EPwm3Regs, &EPwm4Regs};
```

Step 3. MEP_ScaleFactor Initialization

After power up, the SFO_MepEn(n) function needs a starting Scale Factor value. This value can be conveniently determined by using one of the ePWM modules to run the SFO_MepDis(n) function prior to configuring its PWM outputs for the application. SFO_MepDis(n) function does not require a starting Scale Factor value.

As part of the one-time initialization code, include the following:

Example 14-5. Initializing With a Scale Factor Value

```
//     MEP_ScaleFactor variables initialized using function SFO_MepDis
while (MEP_ScaleFactor[1] == 0) SFO_MepDis(1);    //SFO for HRPWM1
while (MEP_ScaleFactor[2] == 0) SFO_MepDis(2);    //SFO for HRPWM2
while (MEP_ScaleFactor[3] == 0) SFO_MepDis(3);    //SFO for HRPWM3
while (MEP_ScaleFactor[4] == 0) SFO_MepDis(4);    //SFO for HRPWM4

// Initialize a common seed variable MEP_ScaleFactor[0] // required for all SFO functions
MEP_ScaleFactor[0] = MEP_ScaleFactor[1]; //Common variable for SFOMepEN(n) function
```

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Step 4. Application Code

While the application is running, fluctuations in both device temperature and supply voltage may be expected. To be sure that optimal Scale Factors are used for each ePWM module, the SFO function should be re-run periodically as part of a slower back-ground loop. Some examples of this are shown here.

Example 14-6. SFO Function Calls

```
main()
{

    //  User code
    // Case1: ePWM1,2,3,4 are running in HRPWM mode
        SFO_MepEn(1);                       // Each of these of function enables
        SFO_MepEn(2);                       // the respective MEP diagnostic logic
        SFO_MepEn(3);                       // and returns MEP Scale factor value
        SFO_MepEn(4);

        MEP_SF1 = MEP_ScaleFactor[1];       // used for ePWM1
        MEP_SF2 = MEP_ScaleFactor[2];       // used for ePWM2
        MEP_SF3 = MEP_ScaleFactor[3];       // used for ePWM3
        MEP_SF4 = MEP_ScaleFactor[4];       // used for ePWM4
    // Case2:ePWM1,2,3 only are running in HRPWM mode.
                One of the ePWM channel(as an example ePWM4) is used as for
                Scale factor calibration
   // Here minimum duty cycle limitation is 3 clock cycles.
   //
   // HRPWM 4 MEP diagnostics circuit is used to estimate the MEP steps
   // with the assumption that all HRPWM channels behave similarly
   // though may not be identical.
        SFO_MepDis(4);                     // MEP steps using ePWM4
        MEP_SF1 = MEP_ScaleFactor[4];      // used for ePWM1
        MEP_SF2 = MEP_SF1                  // used for ePWM2
        MEP_SF3 = MEP_SF1                  // used for ePWM3
        MEP_SF4 = MEP_SF1                  // used for ePWM4
 }
```

14.2.2.10.6.4 SFO_TI_Build_V5 Library Routines

In SFO_TI_Build_V5.lib, the diagnostic software has been optimized to use less memory, to minimize the calibration time, and to support up to 16 HRPWM channels. Table 14-42 provides functional description of the two SFO library routines in SFO_TI_Build_V5.lib.

Table 14-42. SFO V5 Library Routines

Function	Description
int SFO_MepDis_V5 (n)	**Scale Factor Optimizer V5 with MEP Disabled** This routine is very similar to the SFO_MepDis() routine in the original SFO library, but with one change. It now returns a 1 when MEP disabled calibration is complete, or a 0 while calibration is still running. This function runs faster than the SFO_MepEn _V5() routine and cannot be used on an ePWM channel while HRPWM capabilities are enabled for that channel. If there is a spare ePWM channel available in the system, SFO_MepDis_V5() can be run for that channel, and the resulting MEP_ScaleFactor[n] value can be copied into the MEP_ScaleFactor[n] for all other channels. Because the MEP step behavior in a particular piece of silicon is similar on all HRPWM channels with regard to temperature and voltage, using one dedicated HRPWM channel for calibration by calling the SFO_MepDis_V5 function will reduce software overhead. The function returns a value in the variable array: MEP_ScaleFactor[n] = Number of MEP steps/SYSCLKOUT If TBCLK is not equal to SYSCLKOUT, then the returned value must be adjusted to reflect the correct TBCLK: MEP steps per TBCLK = MEP_ScaleFactor[n] × (SYSCLKOUT/TBCLK) **Constraints when using this function:** • MEP diagnostics logic uses SYSCLKOUT and not TBCLK. Hence, the SYSCLKOUT restriction is an important constraint. • If TBCLK does not equal SYSCLKOUT, the TBCLK frequency must be great enough so that MEP steps per TBCLK do not exceed 255. This is due to the restriction that there can be no more than 255 MEP steps in a coarse step. • This function cannot be run on an ePWM channel with HRPWM capabilities enabled. **Usage:** • If one of the ePWM modules is running in normal ePWM mode, then it can be used to run the SFO diagnostics function. Here, the single MEP_ScaleFactor value obtained for that channel can be copied and used as the MEP_ScaleFactor for the other ePWM modules which are running HRPWM mode. This assumes that all HRPWM modules' MEP steps are similar but may not be identical. • This routine returns a 1 when calibration is finished on the specified channel or a 0 if calibration is still running. • The ePWM module that is not active in HRPWM mode is still fully operational in conventional PWM mode and can be used to drive PWM pins. The SFO function only makes use of the MEP diagnostics logic in the HRPWM circuitry. • SFO_MepDis_V5(n) function does not require a starting Scale Factor value. • The other ePWM modules operating in HRPWM mode incur only a 3-cycle minimum duty cycle limitation.

Table 14-42. SFO V5 Library Routines (continued)

Function	Description
int SFO_MepEn_V5 (n)	**Scale Factor Optimizer V5 with MEP Enabled** This function runs slower than the SFO_MepDis_V5() routine and runs SFO diagnostics on an ePWM channel with HRPWM capabilities enabled for that channel. The function returns a value in the variable array: MEP_ScaleFactor[n] = Number of MEP steps/SYSCLKOUT = Number of MEP steps/TBCLK **Constraints when using this function:** • This routine must be run on one channel at a time and cannot be run on multiple channels concurrently. When it has finished updating the MEP_ScaleFactor for a channel, it will return a 1. If it is still calibrating, it will return a 0. A background loop should exist in the user code which calls SFO_MepEn_V5(n) repetitively until it returns a 1. Then the function can be called for the next channel .[(1)] **NOTE:** Unlike the original SFO_MepEn(n) routine, this routine cannot run on multiple channels concurrently. Do not call SFO_MepEn_V5(n) for another channel until the function returns a 1 for the current channel. Otherwise, the MEP_ScaleFactor for both channels will become corrupted. SFO_MepEn_V5(n) in *SFO_TI_Build_V5.lib* supports only the following HRPWM configuration: – HRCNFG[HRLOAD] = 0 (load on CTR = 0) – HRCNFG[EDGMODE] = 10 (falling edge MEP control) An upgraded version of SFO_MepEn_V5(n) in *SFO_TI_Build_V5B.lib* supports all available HRPWM configurations. When using this version, the HRCNFG register must be initialized with the appropriate configuration after calling SFO_MepDis_V5(n) to seed the MEP_ScaleFactor[n] and prior to calling SFO_MepEn_V5(n). • MEP diagnostics logic uses SYSCLKOUT and not TBCLK. Hence, the SYSCLKOUT restriction is an important constraint. **Usage:** • After calling SFO_MepDis(n) to seed MEP_ScaleFactor[n], and prior to using the SFO_MepEn_V5(n) function in *SFO_TI_Build_V5B.lib*, the HRCNFG register must be initialized with the desired HRPWM configuration. Otherwise, calibration will not be initiated, and calls to SFO_MepEn_V5(n) will continuously return zero. • The SFO_MepEn_V5(n) function requires a starting scale factor value, MEP_ScaleFactor[0]. MEP_ScaleFactor[0] needs to be initialized to a typical MEP step size value. To do this, SFO_MepDis_V5(n) can be run on an ePWM channel while the HRPWM is disabled, and the resulting MEP_ScaleFactor[n] value can be copied into MEP_ScaleFactor[0]. • If there are drastic environmental changes to your system (i.e. temperature/voltage), it is generally a good idea to re-seed MEP_ScaleFactor[0] with a new typical MEP step size value for the changed conditions. • Because SFO_MepEn_V5(n) can be run on only one channel at a time, it is only recommended for systems where there are no spare HRPWM channels available, so SFO calibration must be performed on all channels with HRPWM capabilities enabled. In this case, a 6-cycle MEP inactivity zone exists at the start of each PWM period on all HRPWM channels. See Section 14.2.2.10.5.3 on duty cycle range limitation. • The function returns: – A 1 when it has finished SFO calibration for the current channel – A 0 when SFO diagnostics are still running for the channel

(1) If SFO calibration must be run on multiple channels at a time while HRPWM capabilities are enabled, the previous version of the SFO library, SFO_TI_Build.lib, which uses more memory resources, can be used instead, and SFO_MepEn(n) can run concurrently for up to 4 ePWM channels with HRPWM enabled.

Table 14-42. SFO V5 Library Routines (continued)

Function	Description
	– A 2 as an error indicator after calibration has completed if the resulting MEP_ScaleFactor for the channel differs from the original MEP_ScaleFactor[0] seed value by more than +/- 15. The function must be called repetitively before it will return a 1. This takes a longer time to complete than the SFO_MepDis_V5(n) calibration. If it returns a 2, the MEP_ScaleFactor for the channel has finished updating and is outside the typical drift range of MEP_ScaleFactor[0] +/-15 even with large temperature and voltage variations. If the reason for the large difference between the seed and the channel scale factor is known and acceptable, the user may choose to ignore the return of 2, and treat it as a return value of 1, indicating that calibration is complete. Otherwise, if the large difference is unexpected, there are steps to take to remedy the error: 1. Check your code to ensure SFO_MepEn_V5(n) is not being called on more than one channel at a time. 2. If the above is not effective, run SFO_MepDis_V5(n) again and re-seed Mep_ScaleFactor[0]. 3. If neither of the above 2 steps work, there may be a system problem. The application firmware should perform a shutdown or an appropriate recovery procedure. • If all ePWM modules are using the same TBCLK prescaler, then it is possible to run the SFO_MepEn_V5(n) function for only one ePWM module and to use the MEP_ScaleFactor value for that module for the other modules also. In this case only one ePWM module incurs the 6-cycle duty limitation, and the remaining modules incur only a 3-cycle minimum duty limitation. This assumes that all HRPWM modules' MEP steps are similar but may not be identical.

14.2.2.10.6.5 SFO_TI_Build_V5 Software Usage

Software library functions int SFO_MepEn_V5(int n) and int SFO_MepDis_V5(int n) calculate the MEP scale factor for ePWMn modules, where n= the ePWM channel number. The scale factor value, which represents the number of micro-steps available in a system clock period, is returned in a global array of integer values called MEP_ScaleFactor[x], where x is the maximum number of HRPWM channels for a device plus one. For example, if the maximum number of HRPWM channels for a device is 16, the scale factor array would be MEP_ScaleFactor[17]. Both SFO_MepEn_V5 and SFO_MepDis_V5 themselves also return a 1 when calibration has completed, indicating the MEP_ScaleFactor has been successfully updated for the channel, and a 0 when calibration is still on-going. A return of 2 represents an out-of-range error.

Table 14-43. Software Functions

Software functional calls	Functional Description
int SFO_MepDis_V5(int n)[(1)]	
status = SFO_MepDis_V5(1)	The scale factor in MEP_ScaleFactor[1] is updated when status = 1
status = SFO_MepDis_V5(2)	The scale factor in MEP_ScaleFactor[2] is updated when status = 1
...	...
status = SFP_MepDis_V5(16)	The scale factor in MEP_ScaleFactor[16] is updated when status = 1 or 2
int SFO_MepEn_V5(int n)[(1)]	
status = SFO_MepEn_V5(1);	The scale factor in MEP_ScaleFactor[1] is updated when status = 1 or 2
status = SFO_MepEn_V5(2);	The scale factor in MEP_ScaleFactor[2] is updated when status = 1 or 2
...	...
status = SFO_MepEn_V5(16);	The scale factor in MEP_ScaleFactor[16] is updated when status = 1 or 2

(1) MEP_ScaleFactor[0] is a starting seed value used by the SFO software functions internally.

To use the HRPWM feature of the ePWMs, it is recommended that the SFO functions in TI_Build_V5.lib be used as described here. For different devices that may have fewer HRPWM channels, modifications will be required in Step 1 and Step 2.

NOTE: The following example assumes there are four ePWM instances that contain the HRPWM submodule in the device. See your device-specific data manual to determine the number of ePWM instances that contain the HRPWM submodule.

Step 1. Add Include Files

The SFO_V5.h file needs to be included as follows. This include file is mandatory when using the SFO V5 library functions.

Example 14-7. A Sample of How to Add Include Files

```
#include SFO_V5.h                    // SFO V5 lib functions (needed for HRPWM)
```

Step 2. Define Number of HRPWM Channels Used

In the SFO_V5.h file, the maximum number of HRPWM's used for a particular device must be defined. PWM_CH must equal the number of HRPWM channels plus 1.

To save static variable memory, fewer than the maximum number of HRPWM channels may be defined with some caution. To do this, PWM_CH can be set to the largest ePWM channel number plus 1. For instance, if only ePWM1A and ePWM2A channels are required as HRPWM channels, PWM_CH can be set to 3. However, if only ePWM15A and ePWM16A channels are required as HRPWM channels, PWM_CH must still be set to 17.

Copyright © 2011, Texas Instruments Incorporated

Example 14-8. Defining Number of HRPWM Channels Used (Plus 1)

```
 // SFO_V5.H
// NOTE: THIS IS A VERY IMPORTANT STEP. PWM_CH MUST BE DEFINED FIRST BEFORE
//       BUILDING CODE.

#define PWM_CH 17 // Maximum of 16 HRPWM channels (16+1=17)
```

Step 3. Element Declaration

Declare an array of integer variables with a length equal to PWM_CH, and an array of pointers to EPWM register structures. The array of pointers will include pointers for up to 16 EPWM register structures plus one dummy pointer in location EPWM[0] for a device with 16 EPWM channels. Likewise, it will include pointers for up to 4 EPWM register structures plus 1 for a device with 4 EPWM registers and up to 3 EPWM register structures plus 1 for a device with 3 EPWM registers.

Example 14-9. Declaring Elements Required by SFO_TI_Build_V5.lib

```
int MEP_ScaleFactor[PWM_CH] = {0,0,0,0,0, // Scale factor values for ePWM 1-16
                               0,0,0,0, // and MEP_ScaleFactor[0]
                               0,0,0,0, // For fewer HRPWM channels, there
                               0,0,0,0};// will be fewer zeros initialized.

// Declare a volatile array of pointers to EPWM Register structures.
// Only point to registers that exist. If a device has only 6 EPWMs (PWM_CH is 7),
// the array will include pointers for up to 6 EPWM register structures plus one
// dummy pointer in the ePWM[0] location.
volatile struct EPWM_REGS *ePWM[PWM_CH]  {&EPwm1Regs, &EPwm1Regs, &EPwm2Regs,
&EPwm3Regs, &EPwm4Regs, &EPwm5Regs, &EPwm6Regs, &EPwm7Regs,
&EPwm8Regs, &EPwm9Regs, &EPwm10Regs, &EPwm11Regs, &EPwm12Regs,
&EPwm13Regs, &EPwm14Regs, &EPwm15Regs, &EPwm16Regs};
```

Step 4. MEP_ScaleFactor Initialization

After power up, the SFO_MepEn_V5(n) function needs a typical scale factor starting seed value in MEP_ScaleFactor[0]. This value can be conveniently determined using one of the ePWM modules to run the SFO_MepDis_V5(n) function prior to initializing the PWM settings for the application. The SFO_MepDis_V5(n) function does not require a starting scale factor value.

As part of the one-time initialization code, include the following:

Example 14-10. Initialization With a Scale Factor Value

```
// MEP_ScaleFactor variables initialized using function SFO_MepDis_V5
Uint16 I;
for (I=1; i<PWM_CH; I++)        // For channels 1-16
{
    while (SFO_MepDis_V5(I)==0); // Calls MepDis until MEP_ScaleFactor updated
}

// Initialize MEP_ScaleFactor[0] with a typical MEP seed value
// required for SFO_MepEn_V5
    MEP_ScaleFactor[0] = MEP_ScaleFactor[1];
```

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Step 5. Application Code

While the application is running, fluctuations in both device temperature and supply voltage may be expected. To be sure that optimal scale factors are used for each ePWM module, the SFO function should be re-run periodically as part of a slower background loop. Some examples of this are shown here.

Example 14-11. SFO Function Calls

```
main()
{
   Uint16 current_ch = 1; // keeps track of current HRPWM channel being calibrated
   Uint16 status;

  //  User code

  //  Case 1: All ePWMs are running in HRPWM mode
  //          Here, the minimum duty cycle limitation is 6 clock cycles.

        status = SFO_MepEn_V5(current_ch); // MepEn called here
        if (status ==1)                    // if MEP_ScaleFactor has been updated
        {
            current_ch++;                  // move on to the next channel
        }

        else if (status==2)                // if MEP_ScaleFactor differs from
        {                                  // MEP_ScaleFactor[0] seed by more than
             error();                      // +/-15, flag an error
        }
        if (current_ch==PWM_CH)            // if last channel has been reached
        {
            current_ch = 1;                // go back to channel 1
        }

  //  Case 2: all ePWMs except one are running in HRPWM mode.
  //          One of the ePWM channels (ePWM16 in this example) is used
  //          for SFO_MepDis_V5 scale factor calibration.
  //          Here, the minimum duty cycle limitation is 3 clock cycles.

  //          HRPWM16 diagnostics circuitry is used to estimate the MEP steps
  //          with the assumption that all HRPWM channels behave similarly
  //          though they may not be identical.

    while (SFO_MepDis_V5(16)==0); // wait until MEP_ScaleFactor[16] updated
    for (I=1; I<(PWM_CH-1); I++)        // Update scale factors for ePWM 1-15.
    {
         MEP_ScaleFactor[i] = MEP_ScaleFactor[16];
```

14.2.3 Use Cases

An ePWM module has all the local resources necessary to operate completely as a standalone module or to operate in synchronization with other identical ePWM modules.

14.2.3.1 Overview of Multiple Modules

Previously in this user's guide, all discussions have described the operation of a single module. To facilitate the understanding of multiple modules working together in a system, the ePWM module described in reference is represented by the more simplified block diagram shown in Figure 14-50. This simplified ePWM block shows only the key resources needed to explain how a multiswitch power topology is controlled with multiple ePWM modules working together.

Figure 14-50. Simplified ePWM Module

14.2.3.2 Key Configuration Capabilities

The key configuration choices available to each module are as follows:

- Options for SyncIn
  - Load own counter with phase register on an incoming sync strobe—enable (EN) switch closed
  - Do nothing or ignore incoming sync strobe—enable switch open
  - Sync flow-through - SyncOut connected to SyncIn
  - Master mode, provides a sync at PWM boundaries—SyncOut connected to CTR = PRD
  - Master mode, provides a sync at any programmable point in time—SyncOut connected to CTR = CMPB
  - Module is in standalone mode and provides No sync to other modules—SyncOut connected to X (disabled)
- Options for SyncOut
  - Sync flow-through - SyncOut connected to SyncIn
  - Master mode, provides a sync at PWM boundaries—SyncOut connected to CTR = PRD
  - Master mode, provides a sync at any programmable point in time—SyncOut connected to CTR = CMPB
  - Module is in standalone mode and provides No sync to other modules—SyncOut connected to X (disabled)

For each choice of SyncOut, a module may also choose to load its own counter with a new phase value on a SyncIn strobe input or choose to ignore it, i.e., via the enable switch. Although various combinations are possible, the two most common—master module and slave module modes—are shown in Figure 14-51.

14.2.3.3 Controlling Multiple Buck Converters With Independent Frequencies

One of the simplest power converter topologies is the buck. A single ePWM module configured as a master can control two buck stages with the same PWM frequency. If independent frequency control is required for each buck converter, then one ePWM module must be allocated for each converter stage. Figure 14-52 shows four buck stages, each running at independent frequencies. In this case, all four ePWM modules are configured as Masters and no synchronization is used. Figure 14-53 shows the waveforms generated by the setup shown in Figure 14-52; note that only three waveforms are shown, although there are four stages.

Figure 14-52. Control of Four Buck Stages. Here $F_{PWM1} \neq F_{PWM2} \neq F_{PWM3} \neq F_{PWM4}$

NOTE: Θ = X indicates value in phase register is a "don't care"

```

14.2.3.4 Controlling Multiple Buck Converters With Same Frequencies

If synchronization is a requirement, ePWM module 2 can be configured as a slave and can operate at integer multiple (N) frequencies of module 1. The sync signal from master to slave ensures these modules remain locked. Figure 14-54 shows such a configuration; Figure 14-55 shows the waveforms generated by the configuration.

14.2.3.5 Controlling Multiple Half H-Bridge (HHB) Converters

Topologies that require control of multiple switching elements can also be addressed with these same ePWM modules. It is possible to control a Half-H bridge stage with a single ePWM module. This control can be extended to multiple stages. Figure 14-56 shows control of two synchronized Half-H bridge stages where stage 2 can operate at integer multiple (N) frequencies of stage 1. Figure 14-57 shows the waveforms generated by the configuration shown in Figure 14-56.

Module 2 (slave) is configured for Sync flow-through; if required, this configuration allows for a third Half-H bridge to be controlled by PWM module 3 and also, most importantly, to remain in synchronization with master module 1.

14.2.3.6 Controlling Dual 3-Phase Inverters for Motors (ACI and PMSM)

The idea of multiple modules controlling a single power stage can be extended to the 3-phase Inverter case. In such a case, six switching elements can be controlled using three PWM modules, one for each leg of the inverter. Each leg must switch at the same frequency and all legs must be synchronized. A master + two slaves configuration can easily address this requirement. Figure 14-58 shows how six PWM modules can control two independent 3-phase Inverters; each running a motor.

As in the cases shown in the previous sections, we have a choice of running each inverter at a different frequency (module 1 and module 4 are masters as in Figure 14-58), or both inverters can be synchronized by using one master (module 1) and five slaves. In this case, the frequency of modules 4, 5, and 6 (all equal) can be integer multiples of the frequency for modules 1, 2, 3 (also all equal).

14.2.3.7 Practical Applications Using Phase Control Between PWM Modules

So far, none of the examples have made use of the phase register (TBPHS). It has either been set to zero or its value has been a don't care. However, by programming appropriate values into TBPHS, multiple PWM modules can address another class of power topologies that rely on phase relationship between legs (or stages) for correct operation. As described in the TB module section, a PWM module can be configured to allow a SyncIn pulse to cause the TBPHS register to be loaded into the TBCNT register. To illustrate this concept, Figure 14-60 shows a master and slave module with a phase relationship of 120°, that is, the slave leads the master.

Figure 14-60. Configuring Two PWM Modules for Phase Control

Figure 14-61 shows the associated timing waveforms for this configuration. Here, TBPRD = 600 for both master and slave. For the slave, TBPHS = 200 (200/600 × 360° = 120°). Whenever the master generates a SyncIn pulse (CTR = PRD), the value of TBPHS = 200 is loaded into the slave TBCNT register so the slave time-base is always leading the master's time-base by 120°.

Figure 14-61. Timing Waveforms Associated With Phase Control Between 2 Modules

14.2.3.8 Controlling a 3-Phase Interleaved DC/DC Converter

A popular power topology that makes use of phase-offset between modules is shown in Figure 14-62. This system uses three PWM modules, with module 1 configured as the master. To work, the phase relationship between adjacent modules must be F = 120°. This is achieved by setting the slave TBPHS registers 2 and 3 with values of 1/3 and 2/3 of the period value, respectively. For example, if the period register is loaded with a value of 600 counts, then TBPHS (slave 2) = 200 and TBPHS (slave 3) = 400. Both slave modules are synchronized to the master 1 module.

This concept can be extended to four or more phases, by setting the TBPHS values appropriately. The following formula gives the TBPHS values for N phases:

TBPHS(N,M) = (TBPRD/N) × (M - 1)

Where:

N = number of phases

M = PWM module number

For example, for the 3-phase case (N = 3), TBPRD = 600,

TBPHS(3,2) = (600/3) × (2 - 1) = 200 × 1 = 200 (Phase value for Slave module 2)

TBPHS(3,3) = (600/3) × (3 - 1) = 200 × 2 = 400 (Phase value for Slave module 3)

Figure 14-63 shows the waveforms for the configuration in Figure 14-62.

14.2.3.9 Controlling Zero Voltage Switched Full Bridge (ZVSFB) Converter

The example given in Figure 14-64 assumes a static or constant phase relationship between legs (modules). In such a case, control is achieved by modulating the duty cycle. It is also possible to dynamically change the phase value on a cycle-by-cycle basis. This feature lends itself to controlling a class of power topologies known as *phase-shifted full bridge*, or *zero voltage switched full bridge.* Here the controlled parameter is not duty cycle (this is kept constant at approximately 50 percent); instead it is the phase relationship between legs. Such a system can be implemented by allocating the resources of two PWM modules to control a single power stage, which in turn requires control of four switching elements. Figure 14-65 shows a master/slave module combination synchronized together to control a full H-bridge. In this case, both master and slave modules are required to switch at the same PWM frequency. The phase is controlled by using the slave's phase register (TBPHS). The master's phase register is not used and therefore can be initialized to zero.

14.3 Enhanced Capture (eCAP) Module

14.3.1 Introduction

14.3.1.1 Purpose of the Peripheral

Uses for eCAP include:

- Sample rate measurements of audio inputs
- Speed measurements of rotating machinery (for example, toothed sprockets sensed via Hall sensors)
- Elapsed time measurements between position sensor pulses
- Period and duty cycle measurements of pulse train signals
- Decoding current or voltage amplitude derived from duty cycle encoded current/voltage sensors

14.3.1.2 Features

The eCAP module includes the following features:

- 32-bit time base counter
- 4-event time-stamp registers (each 32 bits)
- Edge polarity selection for up to four sequenced time-stamp capture events
- Interrupt on either of the four events
- Single shot capture of up to four event time-stamps
- Continuous mode capture of time-stamps in a four-deep circular buffer
- Absolute time-stamp capture
- Difference (Delta) mode time-stamp capture
- All above resources dedicated to a single input pin
- When not used in capture mode, the ECAP module can be configured as a single channel PWM output

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

14.3.2 Functional Description

The eCAP module represents one complete capture channel that can be instantiated multiple times depending on the target device. In the context of this guide, one eCAP channel has the following independent key resources:

- Dedicated input capture pin
- 32-bit time base counter
- 4 × 32-bit time-stamp capture registers (CAP1-CAP4)
- 4-stage sequencer (Modulo4 counter) that is synchronized to external events, ECAP pin rising/falling edges.
- Independent edge polarity (rising/falling edge) selection for all 4 events
- Input capture signal prescaling (from 2-62)
- One-shot compare register (2 bits) to freeze captures after 1 to 4 time-stamp events
- Control for continuous time-stamp captures using a 4-deep circular buffer (CAP1-CAP4) scheme
- Interrupt capabilities on any of the 4 capture events

Multiple identical eCAP modules can be contained in a system as shown in Figure 14-66. The number of modules is device-dependent and is based on target application needs. In this chapter, the letter x within a signal or module name is used to indicate a generic eCAP instance on a device.

Figure 14-66. Multiple eCAP Modules

14.3.2.1 Capture and APWM Operating Mode

You can use the eCAP module resources to implement a single-channel PWM generator (with 32 bit capabilities) when it is not being used for input captures. The counter operates in count-up mode, providing a time-base for asymmetrical pulse width modulation (PWM) waveforms. The CAP1 and CAP2 registers become the active period and compare registers, respectively, while CAP3 and CAP4 registers become the period and capture shadow registers, respectively. Figure 14-67 is a high-level view of both the capture and auxiliary pulse-width modulator (APWM) modes of operation.

Figure 14-67. Capture and APWM Modes of Operation

(1) A single pin is shared between CAP and APWM functions. In capture mode, it is an input; in APWM mode, it is an output.

(2) In APWM mode, writing any value to CAP1/CAP2 active registers also writes the same value to the corresponding shadow registers CAP3/CAP4. This emulates immediate mode. Writing to the shadow registers CAP3/CAP4 invokes the shadow mode.

14.3.2.2.1 Event Prescaler

An input capture signal (pulse train) can be prescaled by N = 2-62 (in multiples of 2) or can bypass the prescaler. This is useful when very high frequency signals are used as inputs. Figure 14-69 shows a functional diagram and Figure 14-70 shows the operation of the prescale function.

Figure 14-69. Event Prescale Control

(1) When a prescale value of 1 is chosen (ECCTL1[13:9] = 0000) the input capture signal by-passes the prescale logic completely.

Figure 14-70. Prescale Function Waveforms

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

14.3.2.2.2 Edge Polarity Select and Qualifier

- Four independent edge polarity (rising edge/falling edge) selection multiplexers are used, one for each capture event.
- Each edge (up to 4) is event qualified by the Modulo4 sequencer.
- The edge event is gated to its respective CAP*n* register by the Mod4 counter. The CAP*n* register is loaded on the falling edge.

14.3.2.2.3 Continuous/One-Shot Control

- The Mod4 (2 bit) counter is incremented via edge qualified events (CEVT1-CEVT4).
- The Mod4 counter continues counting (0->1->2->3->0) and wraps around unless stopped.
- A 2-bit stop register is used to compare the Mod4 counter output, and when equal stops the Mod4 counter and inhibits further loads of the CAP1-CAP4 registers. This occurs during one-shot operation.

The continuous/one-shot block (Figure 14-71) controls the start/stop and reset (zero) functions of the Mod4 counter via a mono-shot type of action that can be triggered by the stop-value comparator and re-armed via software control.

Once armed, the eCAP module waits for 1-4 (defined by stop-value) capture events before freezing both the Mod4 counter and contents of CAP1-4 registers (time-stamps).

Re-arming prepares the eCAP module for another capture sequence. Also re-arming clears (to zero) the Mod4 counter and permits loading of CAP1-4 registers again, providing the CAPLDEN bit is set.

In continuous mode, the Mod4 counter continues to run (0->1->2->3->0, the one-shot action is ignored, and capture values continue to be written to CAP1-4 in a circular buffer sequence.

Figure 14-71. Continuous/One-shot Block Diagram

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

14.3.2.2.4 32-Bit Counter and Phase Control

This counter (Figure 14-72) provides the time-base for event captures, and is clocked via the system clock.

A phase register is provided to achieve synchronization with other counters, via a hardware and software forced sync. This is useful in APWM mode when a phase offset between modules is needed.

On any of the four event loads, an option to reset the 32-bit counter is given. This is useful for time difference capture. The 32-bit counter value is captured first, then it is reset to 0 by any of the LD1-LD4 signals.

Figure 14-72. Counter and Synchronization Block Diagram

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

14.3.2.2.5 CAP1-CAP4 Registers

These 32-bit registers are fed by the 32-bit counter timer bus, CTR[0-31] and are loaded (capture a time-stamp) when their respective LD inputs are strobed.

Loading of the capture registers can be inhibited via control bit CAPLDEN. During one-shot operation, this bit is cleared (loading is inhibited) automatically when a stop condition occurs, StopValue = Mod4.

CAP1 and CAP2 registers become the active period and compare registers, respectively, in APWM mode.

CAP3 and CAP4 registers become the respective shadow registers (APRD and ACMP) for CAP1 and CAP2 during APWM operation.

14.3.2.2.6 Interrupt Control

An Interrupt can be generated on capture events (CEVT1-CEVT4, CTROVF) or APWM events (CTR = PRD, CTR = CMP). See Figure 14-73.

A counter overflow event (FFFF FFFFh->0000 0000h) is also provided as an interrupt source (CTROVF).

The capture events are edge and sequencer qualified (that is, ordered in time) by the polarity select and Mod4 gating, respectively.

One of these events can be selected as the interrupt source (from the eCAP*n* module) going to the interrupt controller.

Seven interrupt events (CEVT1, CEVT2, CEVT3, CEVT4, CNTOVF, CTR = PRD, CTR = CMP) can be generated. The interrupt enable register (ECEINT) is used to enable/disable individual interrupt event sources. The interrupt flag register (ECFLG) indicates if any interrupt event has been latched and contains the global interrupt flag bit (INT). An interrupt pulse is generated to the interrupt controller only if any of the interrupt events are enabled, the flag bit is 1, and the INT flag bit is 0. The interrupt service routine must clear the global interrupt flag bit and the serviced event via the interrupt clear register (ECCLR) before any other interrupt pulses are generated. You can force an interrupt event via the interrupt force register (ECFRC). This is useful for test purposes.

14.3.2.2.7 Shadow Load and Lockout Control

In capture mode, this logic inhibits (locks out) any shadow loading of CAP1 or CAP2 from APRD and ACMP registers, respectively.

In APWM mode, shadow loading is active and two choices are permitted:

- Immediate - APRD or ACMP are transferred to CAP1 or CAP2 immediately upon writing a new value.
- On period equal, CTR[31:0] = PRD[31:0]

NOTE: The CEVT1, CEVT2, CEVT3, CEVT4 flags are only active in capture mode (ECCTL2[CAP/APWM == 0]). The CTR = PRD, CTR = CMP flags are only valid in APWM mode (ECCTL2[CAP/APWM == 1]). CNTOVF flag is valid in both modes.

14.3.2.2.8 APWM Mode Operation

Main operating highlights of the APWM section:

- The time-stamp counter bus is made available for comparison via 2 digital (32-bit) comparators.
- When CAP1/2 registers are not used in capture mode, their contents can be used as Period and Compare values in APWM mode.
- Double buffering is achieved via shadow registers APRD and ACMP (CAP3/4). The shadow register contents are transferred over to CAP1/2 registers either immediately upon a write, or on a CTR = PRD trigger.
- In APWM mode, writing to CAP1/CAP2 active registers will also write the same value to the corresponding shadow registers CAP3/CAP4. This emulates immediate mode. Writing to the shadow registers CAP3/CAP4 will invoke the shadow mode.
- During initialization, you must write to the active registers for both period and compare. This automatically copies the initial values into the shadow values. For subsequent compare updates, during run-time, you only need to use the shadow registers.

Figure 14-74. PWM Waveform Details Of APWM Mode Operation

The behavior of APWM active-high mode (APWMPOL == 0) is:

```
CMP = 0x00000000, output low for duration of period (0% duty)
CMP = 0x00000001, output high 1 cycle
CMP = 0x00000002, output high 2 cycles
CMP = PERIOD, output high except for 1 cycle (<100% duty)
CMP = PERIOD+1, output high for complete period (100% duty)
CMP > PERIOD+1, output high for complete period
```

The behavior of APWM active-low mode (APWMPOL == 1) is:

```
CMP = 0x00000000, output high for duration of period (0% duty)
CMP = 0x00000001, output low 1 cycle
CMP = 0x00000002, output low 2 cycles
CMP = PERIOD, output low except for 1 cycle (<100% duty)
CMP = PERIOD+1, output low for complete period (100% duty)
```

14.3.3 Use Cases

The following sections will provide Applications examples and code snippets to show how to configure and operate the eCAP module. For clarity and ease of use, below are useful #defines which will help in the understanding of the examples.

```
// ECCTL1 ( ECAP Control Reg 1)
//==========================
// CAPxPOL bits
#define    EC_RISING              0x0
#define    EC_FALLING             0x1

// CTRRSTx bits
#define    EC_ABS_MODE            0x0
#define    EC_DELTA_MODE          0x1

// PRESCALE bits
#define    EC_BYPASS              0x0
#define    EC_DIV1                0x0
#define    EC_DIV2                0x1
#define    EC_DIV4                0x2
#define    EC_DIV6                0x3
#define    EC_DIV8                0x4
#define    EC_DIV10               0x5

// ECCTL2 ( ECAP Control Reg 2)
//==========================
// CONT/ONESHOT bit
#define    EC_CONTINUOUS          0x0
#define    EC_ONESHOT             0x1

// STOPVALUE bit

14.3.3.1 Absolute Time-Stamp Operation Rising Edge Trigger Example

Figure 14-75 shows an example of continuous capture operation (Mod4 counter wraps around). In this figure, TSCTR counts-up without resetting and capture events are qualified on the rising edge only, this gives period (and frequency) information.

On an event, the TSCTR contents (time-stamp) is first captured, then Mod4 counter is incremented to the next state. When the TSCTR reaches FFFF FFFFh (maximum value), it wraps around to 0000 0000h (not shown in Figure 14-75), if this occurs, the CTROVF (counter overflow) flag is set, and an interrupt (if enabled) occurs, CTROVF (counter overflow) Flag is set, and an Interrupt (if enabled) occurs. Captured time-stamps are valid at the point indicated by the diagram, after the 4th event, hence event CEVT4 can conveniently be used to trigger an interrupt and the CPU can read data from the CAP*n* registers.

14.3.3.2 Absolute Time-Stamp Operation Rising and Falling Edge Trigger Example

In Figure 14-76 the eCAP operating mode is almost the same as in the previous section except capture events are qualified as either rising or falling edge, this now gives both period and duty cycle information: Period1 = $t_3 – t_1$, Period2 = $t_5 – t_3$, …etc. Duty Cycle1 (on-time %) = $(t_2 – t_1)$ / Period1 x 100%, etc. Duty Cycle1 (off-time %) = $(t_3 – t_2)$ / Period1 x 100%, etc.

14.3.3.3 Time Difference (Delta) Operation Rising Edge Trigger Example

Figure 14-77 shows how the eCAP module can be used to collect Delta timing data from pulse train waveforms. Here Continuous Capture mode (TSCTR counts-up without resetting, and Mod4 counter wraps around) is used. In Delta-time mode, TSCTR is Reset back to Zero on every valid event. Here Capture events are qualified as Rising edge only. On an event, TSCTR contents (time-stamp) is captured first, and then TSCTR is reset to Zero. The Mod4 counter then increments to the next state. If TSCTR reaches FFFF FFFFh (maximum value), before the next event, it wraps around to 0000 0000h and continues, a CNTOVF (counter overflow) Flag is set, and an Interrupt (if enabled) occurs. The advantage of Delta-time Mode is that the CAP*n* contents directly give timing data without the need for CPU calculations: Period1 = T_1, Period2 = T_2,…etc. As shown in Figure 14-77, the CEVT1 event is a good trigger point to read the timing data, T_1, T_2, T_3, T_4 are all valid here.

14.3.3.4 Time Difference (Delta) Operation Rising and Falling Edge Trigger Example

In Figure 14-78 the eCAP operating mode is almost the same as in previous section except Capture events are qualified as either Rising or Falling edge, this now gives both Period and Duty cycle information: Period1 = $T_1 + T_2$, Period2 = $T_3 + T_4$, …etc Duty Cycle1 (on-time %) = T_1 / Period1 × 100%, etc Duty Cycle1 (off-time %) = T_2 / Period1 × 100%, etc

During initialization, you must write to the active registers for both period and compare. This will then automatically copy the init values into the shadow values. For subsequent compare updates, that is, during run-time, only the shadow registers must be used.

14.3.3.5 Application of the APWM Mode

14.3.3.5.1 Simple PWM Generation (Independent Channel/s) Example

In this example, the eCAP module is configured to operate as a PWM generator. Here a very simple single channel PWM waveform is generated from output pin APWM*n*. The PWM polarity is active high, which means that the compare value (CAP2 reg is now a compare register) represents the on-time (high level) of the period. Alternatively, if the APWMPOL bit is configured for active low, then the compare value represents the off-time.

Figure 14-79. PWM Waveform Details of APWM Mode Operation

ECCTL2	APWMPOL	EC_ACTV_HI
ECCTL2	SYNCI_EN	EC_DISABLE
ECCTL2	SYNCO_SEL	EC_SYNCO_DIS
ECCTL2	TSCTRSTOP	EC_RUN

Example 14-22. Code Snippet for APWM Mode

```
// Code snippet for APWM mode Example 1

// Run Time (Instant 1, e.g. ISR call)
//=====================
   ECAPxRegs.CAP2 = 0x300;      // Set Duty cycle i.e. compare value

// Run Time (Instant 2, e.g. another ISR call)
//=====================
   ECAPxRegs.CAP2 = 0x500;      // Set Duty cycle i.e. compare value
```

14.3.3.5.2 Multichannel PWM Generation with Synchronization Example

Figure 14-80 takes advantage of the synchronization feature between eCAP modules. Here 4 independent PWM channels are required with different frequencies, but at integer multiples of each other to avoid "beat" frequencies. Hence one eCAP module is configured as the Master and the remaining 3 are Slaves all receiving their synch pulse (CTR = PRD) from the master. Note the Master is chosen to have the lower frequency (F1 = 1/20,000) requirement. Here Slave2 Freq = 2 × F1, Slave3 Freq = 4 × F1 and Slave4 Freq = 5 × F1. Note here values are in decimal notation. Also, only the APWM1 output waveform is shown.

   ECAP3Regs.CAP2 = 550;     // Set Duty cycle i.e., compare value = 550
   ECAP4Regs.CAP2 = 6500;    // Set Duty cycle i.e., compare value = 6500
```

14.3.3.5.3 Multichannel PWM Generation with Phase Control Example

In Figure 14-81, the Phase control feature of the APWM mode is used to control a 3 phase Interleaved DC/DC converter topology. This topology requires each phase to be off-set by 120° from each other. Hence if “Leg” 1 (controlled by APWM1) is the reference Leg (or phase), that is, 0°, then Leg 2 need 120° off-set and Leg 3 needs 240° off-set. The waveforms in Figure 14-81 show the timing relationship between each of the phases (Legs). Note eCAP1 module is the Master and issues a sync out pulse to the slaves (modules 2, 3) whenever TSCTR = Period value.

14.3.4 eCAP Module Control and Status Registers

Table 14-71 shows the eCAP module control and status register set. All 32-bit registers are aligned on even address boundaries and are organized in little-endian mode. The 16 least-significant bits of a 32-bit register are located on lowest address (even address).

NOTE: In APWM mode, writing to CAP1/CAP2 active registers also writes the same value to the corresponding shadow registers CAP3/CAP4. This emulates immediate mode. Writing to the shadow registers CAP3/CAP4 invokes the shadow mode.

Table 14-71. Control and Status Register Set

14.3.4.8 ECAP Control Register 2 (ECCTL2)

The ECAP control register 2 (ECCTL2) is shown in Figure 14-89 and described in Table 14-79.

Figure 14-89. ECAP Control Register 2 (ECCTL2)

15				11	10	9	8
Reserved					APWMPOL	CAP/APWM	SWSYNC
R-0					R/W-0	R/W-0	R/W-0

7	6	5	4	3	2	1	0
SYNCO_SEL		SYNCI_EN	TSCTRSTOP	REARM	STOP_WRAP		CONT/ONESHT
R/W-0		R/W-0	R/W-0	R/W-0	R/W-1		R/W-0

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 14-79. ECAP Control Register 2 (ECCTL2) Field Descriptions

Bit	Field	Value	Description
15-11	Reserved	0	Reserved
10	APWMPOL		APWM output polarity select. This is applicable only in APWM operating mode
		0	Output is active high (Compare value defines high time)
		1	Output is active low (Compare value defines low time)
9	CAP/APWM		CAP/APWM operating mode select
		0	ECAP module operates in capture mode. This mode forces the following configuration: • Inhibits TSCTR resets via CTR = PRD event • Inhibits shadow loads on CAP1 and 2 registers • Permits user to enable CAP1-4 register load • ECAP*n*/APWM*n* pin operates as a capture input
		1	ECAP module operates in APWM mode. This mode forces the following configuration: • Resets TSCTR on CTR = PRD event (period boundary • Permits shadow loading on CAP1 and 2 registers • Disables loading of time-stamps into CAP1-4 registers • ECAP*n*/APWM*n* pin operates as a APWM output
8	SWSYNC		Software-forced Counter (TSCTR) Synchronizing. This provides a convenient software method to synchronize some or all ECAP time bases. In APWM mode, the synchronizing can also be done via the CTR = PRD event.
		0	Writing a zero has no effect. Reading always returns a zero
		1	Writing a one forces a TSCTR shadow load of current ECAP module and any ECAP modules down-stream providing the SYNCO_SEL bits are 0,0. After writing a 1, this bit returns to a zero. Note: Selection CTR = PRD is meaningful only in APWM mode; however, you can choose it in CAP mode if you find doing so useful.
7-6	SYNCO_SEL	0-3h	Sync-Out Select
		0	Select sync-in event to be the sync-out signal (pass through)
		1h	Select CTR = PRD event to be the sync-out signal
		2h	Disable sync out signal
		3h	Disable sync out signal
5	SYNCI_EN		Counter (TSCTR) Sync-In select mode
		0	Disable sync-in option
		1	Enable counter (TSCTR) to be loaded from CTRPHS register upon either a SYNCI signal or a S/W force event.
4	TSCTRSTOP		Time Stamp (TSCTR) Counter Stop (freeze) Control
		0	TSCTR stopped
		1	TSCTR free-running

Table 14-79. ECAP Control Register 2 (ECCTL2) Field Descriptions (continued)

Bit	Field	Value	Description
3	RE-ARM		One-Shot Re-Arming Control, that is, wait for stop trigger. Note: The re-arm function is valid in one shot or continuous mode.
		0	Has no effect (reading always returns a 0)
		1	Arms the one-shot sequence as follows: 1) Resets the Mod4 counter to zero 2) Unfreezes the Mod4 counter 3) Enables capture register loads
2-1	STOP_WRAP	0-3h	Stop value for one-shot mode. This is the number (between 1-4) of captures allowed to occur before the CAP(1-4) registers are frozen, that is, capture sequence is stopped. Wrap value for continuous mode. This is the number (between 1-4) of the capture register in which the circular buffer wraps around and starts again.
		0	Stop after Capture Event 1 in one-shot mode. Wrap after Capture Event 1 in continuous mode.
		1h	Stop after Capture Event 2 in one-shot mode. Wrap after Capture Event 2 in continuous mode.
		2h	Stop after Capture Event 3 in one-shot mode. Wrap after Capture Event 3 in continuous mode.
		3h	Stop after Capture Event 4 in one-shot mode. Wrap after Capture Event 4 in continuous mode.
			Notes: STOP_WRAP is compared to Mod4 counter and, when equal, 2 actions occur: • Mod4 counter is stopped (frozen) • Capture register loads are inhibited In one-shot mode, further interrupt events are blocked until re-armed.
0	CONT/ONESHT		Continuous or one-shot mode control (applicable only in capture mode)
		0	Operate in continuous mode
		1	Operate in one-shot mode

14.3.4.9 ECAP Interrupt Enable Register (ECEINT)

The ECAP interrupt enable register (ECEINT) is shown in Figure 14-90 and described in Table 14-80.

The interrupt enable bits (CEVT*n*) block any of the selected events from generating an interrupt. Events will still be latched into the flag bit (ECFLG register) and can be forced/cleared via the ECFRC/ECCLR registers.

The proper procedure for configuring peripheral modes and interrupts is:

1. Disable global interrupts
2. Stop eCAP counter
3. Disable eCAP interrupts
4. Configure peripheral registers
5. Clear spurious eCAP interrupt flags
6. Enable eCAP interrupts
7. Start eCAP counter
8. Enable global interrupts

14.4 Enhanced Quadrature Encoder Pulse (eQEP) Module

14.4.1 Introduction

A single track of slots patterns the periphery of an incremental encoder disk, as shown in Figure 14-95. These slots create an alternating pattern of dark and light lines. The disk count is defined as the number of dark/light line pairs that occur per revolution (lines per revolution). As a rule, a second track is added to generate a signal that occurs once per revolution (index signal: QEPI), which can be used to indicate an absolute position. Encoder manufacturers identify the index pulse using different terms such as index, marker, home position, and zero reference.

Figure 14-95. Optical Encoder Disk

To derive direction information, the lines on the disk are read out by two different photo-elements that "look" at the disk pattern with a mechanical shift of 1/4 the pitch of a line pair between them. This shift is realized with a reticle or mask that restricts the view of the photo-element to the desired part of the disk lines. As the disk rotates, the two photo-elements generate signals that are shifted 90 degrees out of phase from each other. These are commonly called the quadrature QEPA and QEPB signals. The clockwise direction for most encoders is defined as the QEPA channel going positive before the QEPB channel and vise versa as shown in Figure 14-96.

The encoder wheel typically makes one revolution for every revolution of the motor or the wheel may be at a geared rotation ratio with respect to the motor. Therefore, the frequency of the digital signal coming from the QEPA and QEPB outputs varies proportionally with the velocity of the motor. For example, a 2000-line encoder directly coupled to a motor running at 5000 revolutions per minute (rpm) results in a frequency of 166.6 KHz, so by measuring the frequency of either the QEPA or QEPB output, the processor can determine the velocity of the motor.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Figure 14-96. QEP Encoder Output Signal for Forward/Reverse Movement

Legend: N = lines per revolution

Quadrature encoders from different manufacturers come with two forms of index pulse (gated index pulse or ungated index pulse) as shown in Figure 14-97. A nonstandard form of index pulse is ungated. In the ungated configuration, the index edges are not necessarily coincident with A and B signals. The gated index pulse is aligned to any of the four quadrature edges and width of the index pulse and can be equal to a quarter, half, or full period of the quadrature signal.

Figure 14-97. Index Pulse Example

Copyright © 2011, Texas Instruments Incorporated

Some typical applications of shaft encoders include robotics and even computer input in the form of a mouse. Inside your mouse you can see where the mouse ball spins a pair of axles (a left/right, and an up/down axle). These axles are connected to optical shaft encoders that effectively tell the computer how fast and in what direction the mouse is moving.

General Issues: Estimating velocity from a digital position sensor is a cost-effective strategy in motor control. Two different first order approximations for velocity may be written as:

$$v(k) \approx \frac{x(k) - x(k-1)}{T} = \frac{\Delta X}{T} \quad (1)$$

$$v(k) \approx \frac{X}{t(k) - t(k-1)} = \frac{X}{\Delta T} \quad (2)$$

where

v(k): Velocity at time instant k

x(k): Position at time instant k

x(k-1): Position at time instant k - 1

T: Fixed unit time or inverse of velocity calculation rate

ΔX: Incremental position movement in unit time

t(k): Time instant "k"

t(k-1): Time instant "k - 1"

X: Fixed unit position

ΔT: Incremental time elapsed for unit position movement.

Equation 1 is the conventional approach to velocity estimation and it requires a time base to provide unit time event for velocity calculation. Unit time is basically the inverse of the velocity calculation rate.

The encoder count (position) is read once during each unit time event. The quantity [x(k) - x(k-1)] is formed by subtracting the previous reading from the current reading. Then the velocity estimate is computed by multiplying by the known constant 1/T (where T is the constant time between unit time events and is known in advance).

Estimation based on Equation 1 has an inherent accuracy limit directly related to the resolution of the position sensor and the unit time period T. For example, consider a 500-line per revolution quadrature encoder with a velocity calculation rate of 400 Hz. When used for position the quadrature encoder gives a four-fold increase in resolution, in this case, 2000 counts per revolution. The minimum rotation that can be detected is therefore 0.0005 revolutions, which gives a velocity resolution of 12 rpm when sampled at 400 Hz. While this resolution may be satisfactory at moderate or high speeds, for example, 1% error at 1200 rpm, it would clearly prove inadequate at low speeds. In fact, at speeds below 12 rpm, the speed estimate would erroneously be zero much of the time.

At low speed, Equation 2 provides a more accurate approach. It requires a position sensor that outputs a fixed interval pulse train, such as the aforementioned quadrature encoder. The width of each pulse is defined by motor speed for a given sensor resolution. Equation 2 can be used to calculate motor speed by measuring the elapsed time between successive quadrature pulse edges. However, this method suffers from the opposite limitation, as does Equation 1. A combination of relatively large motor speeds and high sensor resolution makes the time interval ΔT small, and thus more greatly influenced by the timer resolution. This can introduce considerable error into high-speed estimates.

For systems with a large speed range (that is, speed estimation is needed at both low and high speeds), one approach is to use Equation 2 at low speed and have the software switch over to Equation 1 when the motor speed rises above some specified threshold.

14.4.2 Functional Description

This section provides the eQEP inputs and functional description.

NOTE: Multiple identical eQEP modules can be contained in a system. The number of modules is device-dependent and is based on target application needs. In this document, the letter x within a signal or module name is used to indicate a generic eQEP instance on a device.

14.4.2.1 EQEP Inputs

The eQEP inputs include two pins for quadrature-clock mode or direction-count mode, an index (or 0 marker), and a strobe input.

- QEPA/XCLK and QEPB/XDIR: These two pins can be used in quadrature-clock mode or direction-count mode.
  - Quadrature-clock Mode: The eQEP encoders provide two square wave signals (A and B) 90 electrical degrees out of phase whose phase relationship is used to determine the direction of rotation of the input shaft and number of eQEP pulses from the index position to derive the relative position information. For forward or clockwise rotation, QEPA signal leads QEPB signal and vice versa. The quadrature decoder uses these two inputs to generate quadrature-clock and direction signals.
  - Direction-count Mode: In direction-count mode, direction and clock signals are provided directly from the external source. Some position encoders have this type of output instead of quadrature output. The QEPA pin provides the clock input and the QEPB pin provides the direction input.
- QEPI: Index or Zero Marker: The eQEP encoder uses an index signal to assign an absolute start position from which position information is incrementally encoded using quadrature pulses. This pin is connected to the index output of the eQEP encoder to optionally reset the position counter for each revolution. This signal can be used to initialize or latch the position counter on the occurrence of a desired event on the index pin.
- QEPS: Strobe Input: This general-purpose strobe signal can initialize or latch the position counter on the occurrence of a desired event on the strobe pin. This signal is typically connected to a sensor or limit switch to notify that the motor has reached a defined position.

14.4.2.2 Functional Description

The eQEP peripheral contains the following major functional units (as shown in Figure 14-98):

- Programmable input qualification for each pin (part of the GPIO MUX)
- Quadrature decoder unit (QDU)
- Position counter and control unit for position measurement (PCCU)
- Quadrature edge-capture unit for low-speed measurement (QCAP)
- Unit time base for speed/frequency measurement (UTIME)
- Watchdog timer for detecting stalls (QWDOG)

14.4.2.3.1 Position Counter Input Modes

Clock and direction input to position counter is selected using the QSRC bit in the eQEP decoder control register (QDECCTL), based on interface input requirement as follows:

- Quadrature-count mode
- Direction-count mode
- UP-count mode
- DOWN-count mode

14.4.2.3.1.1 Quadrature Count Mode

The quadrature decoder generates the direction and clock to the position counter in quadrature count mode.

Direction Decoding— The direction decoding logic of the eQEP circuit determines which one of the sequences (QEPA, QEPB) is the leading sequence and accordingly updates the direction information in the QDF bit in the eQEP status register (QEPSTS). Table 14-85 and Figure 14-100 show the direction decoding logic in truth table and state machine form. Both edges of the QEPA and QEPB signals are sensed to generate count pulses for the position counter. Therefore, the frequency of the clock generated by the eQEP logic is four times that of each input sequence. Figure 14-101 shows the direction decoding and clock generation from the eQEP input signals.

Phase Error Flag— In normal operating conditions, quadrature inputs QEPA and QEPB will be 90 degrees out of phase. The phase error flag (PHE) is set in the QFLG register when edge transition is detected simultaneously on the QEPA and QEPB signals to optionally generate interrupts. State transitions marked by dashed lines in Figure 14-100 are invalid transitions that generate a phase error.

Count Multiplication— The eQEP position counter provides 4x times the resolution of an input clock by generating a quadrature-clock (QCLK) on the rising/falling edges of both eQEP input clocks (QEPA and QEPB) as shown in Figure 14-101.

Reverse Count— In normal quadrature count operation, QEPA input is fed to the QA input of the quadrature decoder and the QEPB input is fed to the QB input of the quadrature decoder. Reverse counting is enabled by setting the SWAP bit in the eQEP decoder control register (QDECCTL). This will swap the input to the quadrature decoder thereby reversing the counting direction.

14.4.2.3.1.2 Direction-count Mode

Some position encoders provide direction and clock outputs, instead of quadrature outputs. In such cases, direction-count mode can be used. QEPA input will provide the clock for position counter and the QEPB input will have the direction information. The position counter is incremented on every rising edge of a QEPA input when the direction input is high and decremented when the direction input is low.

14.4.2.3.1.3 Up-Count Mode

The counter direction signal is hard-wired for up count and the position counter is used to measure the frequency of the QEPA input. Setting of the XCR bit in the eQEP decoder control register (QDECCTL) enables clock generation to the position counter on both edges of the QEPA input, thereby increasing the measurement resolution by 2× factor.

14.4.2.3.1.4 Down-Count Mode

The counter direction signal is hardwired for a down count and the position counter is used to measure the frequency of the QEPA input. Setting of the XCR bit in the eQEP decoder control register (QDECCTL) enables clock generation to the position counter on both edges of a QEPA input, thereby increasing the measurement resolution by 2× factor.

14.4.2.3.2 eQEP Input Polarity Selection

Each eQEP input can be inverted using the in the eQEP decoder control register (QDECCTL[8:5]) control bits. As an example, setting of the QIP bit in QDECCTL inverts the index input.

14.4.2.3.3 Position-Compare Sync Output

The eQEP peripheral includes a position-compare unit that is used to generate the position-compare sync signal on compare match between the position counter register (QPOSCNT) and the position-compare register (QPOSCMP). This sync signal can be output using an index pin or strobe pin of the EQEP peripheral.

Setting the SOEN bit in the eQEP decoder control register (QDECCTL) enables the position-compare sync output and the SPSEL bit in QDECCTL selects either an eQEP index pin or an eQEP strobe pin.

14.4.2.4 Position Counter and Control Unit (PCCU)

The position counter and control unit provides two configuration registers (QEPCTL and QPOSCTL) for setting up position counter operational modes, position counter initialization/latch modes and position-compare logic for sync signal generation.

14.4.2.4.1 Position Counter Operating Modes

Position counter data may be captured in different manners. In some systems, the position counter is accumulated continuously for multiple revolutions and the position counter value provides the position information with respect to the known reference. An example of this is the quadrature encoder mounted on the motor controlling the print head in the printer. Here the position counter is reset by moving the print head to the home position and then position counter provides absolute position information with respect to home position.

In other systems, the position counter is reset on every revolution using index pulse and position counter provides rotor angle with respect to index pulse position.

Position counter can be configured to operate in following four modes

- Position Counter Reset on Index Event
- Position Counter Reset on Maximum Position
- Position Counter Reset on the first Index Event
- Position Counter Reset on Unit Time Out Event (Frequency Measurement)

Copyright © 2011, Texas Instruments Incorporated

In all the above operating modes, position counter is reset to 0 on overflow and to QPOSMAX register value on underflow. Overflow occurs when the position counter counts up after QPOSMAX value. Underflow occurs when position counter counts down after "0". Interrupt flag is set to indicate overflow/underflow in QFLG register.

14.4.2.4.1.1 Position Counter Reset on Index Event (QEPCTL[PCRM] = 00)

If the index event occurs during the forward movement, then position counter is reset to 0 on the next eQEP clock. If the index event occurs during the reverse movement, then the position counter is reset to the value in the QPOSMAX register on the next eQEP clock.

First index marker is defined as the quadrature edge following the first index edge. The eQEP peripheral records the occurrence of the first index marker (QEPSTS[FIMF]) and direction on the first index event marker (QEPSTS[FIDF]) in QEPSTS registers, it also remembers the quadrature edge on the first index marker so that same relative quadrature transition is used for index event reset operation.

For example, if the first reset operation occurs on the falling edge of QEPB during the forward direction, then all the subsequent reset must be aligned with the falling edge of QEPB for the forward rotation and on the rising edge of QEPB for the reverse rotation as shown in Figure 14-102.

The position-counter value is latched to the QPOSILAT register and direction information is recorded in the QEPSTS[QDLF] bit on every index event marker. The position-counter error flag (QEPSTS[PCEF]) and error interrupt flag (QFLG[PCE]) are set if the latched value is not equal to 0 or QPOSMAX. The position-counter error flag (QEPSTS[PCEF]) is updated on every index event marker and an interrupt flag (QFLG[PCE]) will be set on error that can be cleared only through software.

The index event latch configuration QEPCTL[IEL] bits are ignored in this mode and position counter error flag/interrupt flag are generated only in index event reset mode.

Figure 14-102. Position Counter Reset by Index Pulse for 1000 Line Encoder (QPOSMAX = 3999 or F9Fh)

Copyright © 2011, Texas Instruments Incorporated

14.4.2.4.1.2 Position Counter Reset on Maximum Position (QEPCTL[PCRM]=01)

If the position counter is equal to QPOSMAX, then the position counter is reset to 0 on the next eQEP clock for forward movement and position counter overflow flag is set. If the position counter is equal to ZERO, then the position counter is reset to QPOSMAX on the next QEP clock for reverse movement and position counter underflow flag is set. Figure 14-103 shows the position counter reset operation in this mode.

First index marker is defined as the quadrature edge following the first index edge. The eQEP peripheral records the occurrence of the first index marker (QEPSTS[FIMF]) and direction on the first index event marker (QEPSTS[FIDF]) in the QEPSTS registers; it also remembers the quadrature edge on the first index marker so that the same relative quadrature transition is used for the software index marker (QEPCTL[IEL]=11).

14.4.2.4.1.3 Position Counter Reset on the First Index Event (QEPCTL[PCRM] = 10)

If the index event occurs during forward movement, then the position counter is reset to 0 on the next eQEP clock. If the index event occurs during the reverse movement, then the position counter is reset to the value in the QPOSMAX register on the next eQEP clock. Note that this is done only on the first occurrence and subsequently the position counter value is not reset on an index event; rather, it is reset based on maximum position as described in Section 14.4.2.4.1.2.

First index marker is defined as the quadrature edge following the first index edge. The eQEP peripheral records the occurrence of the first index marker (QEPSTS[FIMF]) and direction on the first index event marker (QEPSTS[FIDF]) in QEPSTS registers. It also remembers the quadrature edge on the first index marker so that same relative quadrature transition is used for software index marker (QEPCTL[IEL]=11).

14.4.2.4.1.4 Position Counter Reset on Unit Time out Event (QEPCTL[PCRM] = 11)

In this mode, the QPOSCNT value is latched to the QPOSLAT register and then the QPOSCNT is reset (to 0 or QPOSMAX, depending on the direction mode selected by QDECCTL[QSRC] bits on a unit time event). This is useful for frequency measurement.

14.4.2.4.2 Position Counter Latch

The eQEP index and strobe input can be configured to latch the position counter (QPOSCNT) into QPOSILAT and QPOSSLAT, respectively, on occurrence of a definite event on these pins.

14.4.2.4.2.1 Index Event Latch

In some applications, it may not be desirable to reset the position counter on every index event and instead it may be required to operate the position counter in full 32-bit mode (QEPCTL[PCRM] = 01 and QEPCTL[PCRM] = 10 modes).

In such cases, the eQEP position counter can be configured to latch on the following events and direction information is recorded in the QEPSTS[QDLF] bit on every index event marker.

- Latch on Rising edge (QEPCTL[IEL] = 01)
- Latch on Falling edge (QEPCTL[IEL] = 10)
- Latch on Index Event Marker (QEPCTL[IEL] = 11)

This is particularly useful as an error checking mechanism to check if the position counter accumulated the correct number of counts between index events. As an example, the 1000-line encoder must count 4000 times when moving in the same direction between the index events.

The index event latch interrupt flag (QFLG[IEL]) is set when the position counter is latched to the QPOSILAT register. The index event latch configuration bits (QEPCTZ[IEL]) are ignored when QEPCTL[PCRM] = 00.

Latch on Rising Edge (QEPCTL[IEL] = 01)— The position counter value (QPOSCNT) is latched to the QPOSILAT register on every rising edge of an index input.

Latch on Falling Edge (QEPCTL[IEL] = 10)— The position counter value (QPOSCNT) is latched to the QPOSILAT register on every falling edge of index input.

Latch on Index Event Marker/Software Index Marker (QEPCTL[IEL] = 11)— The first index marker is defined as the quadrature edge following the first index edge. The eQEP peripheral records the occurrence of the first index marker (QEPSTS[FIMF]) and direction on the first index event marker (QEPSTS[FIDF]) in the QEPSTS registers. It also remembers the quadrature edge on the first index marker so that same relative quadrature transition is used for latching the position counter (QEPCTL[IEL] = 11).

Figure 14-104 shows the position counter latch using an index event marker.

14.4.2.4.2.2 Strobe Event Latch

The position-counter value is latched to the QPOSSLAT register on the rising edge of the strobe input by clearing the QEPCTL[SEL] bit.

If the QEPCTL[SEL] bit is set, then the position counter value is latched to the QPOSSLAT register on the rising edge of the strobe input for forward direction and on the falling edge of the strobe input for reverse direction as shown in Figure 14-105.

The strobe event latch interrupt flag (QFLG[SEL]) is set when the position counter is latched to the QPOSSLAT register.

Figure 14-105. Strobe Event Latch (QEPCTL[SEL] = 1)

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

14.4.2.4.3 Position Counter Initialization

The position counter can be initialized using following events:

- Index event
- Strobe event
- Software initialization

Index Event Initialization (IEI)— The QEPI index input can be used to trigger the initialization of the position counter at the rising or falling edge of the index input.

If the QEPCTL[IEI] bits are 10, then the position counter (QPOSCNT) is initialized with a value in the QPOSINIT register on the rising edge of strobe input for forward direction and on the falling edge of strobe input for reverse direction.

The index event initialization interrupt flag (QFLG[IEI]) is set when the position counter is initialized with a value in the QPOSINIT register.

Strobe Event Initialization (SEI)— If the QEPCTL[SEI] bits are 10, then the position counter is initialized with a value in the QPOSINIT register on the rising edge of strobe input.

If the QEPCTL[SEL] bits are 11, then the position counter (QPOSCNT) is initialized with a value in the QPOSINIT register on the rising edge of strobe input for forward direction and on the falling edge of strobe input for reverse direction.

The strobe event initialization interrupt flag (QFLG[SEI]) is set when the position counter is initialized with a value in the QPOSINIT register.

Software Initialization (SWI)— The position counter can be initialized in software by writing a 1 to the QEPCTL[SWI] bit, which will automatically be cleared after initialization.

14.4.2.4.4 eQEP Position-compare Unit

The eQEP peripheral includes a position-compare unit that is used to generate a sync output and/or interrupt on a position-compare match. Figure 14-106 shows a diagram. The position-compare (QPOSCMP) register is shadowed and shadow mode can be enabled or disabled using the QPOSCTL[PSSHDW] bit. If the shadow mode is not enabled, the CPU writes directly to the active position compare register.

Figure 14-106. eQEP Position-compare Unit

In shadow mode, you can configure the position-compare unit (QPOSCTL[PCLOAD]) to load the shadow register value into the active register on the following events and to generate the position-compare ready (QFLG[PCR]) interrupt after loading.

- Load on compare match
- Load on position-counter zero event

Copyright © 2011, Texas Instruments Incorporated

The position-compare match (QFLG[PCM]) is set when the position-counter value (QPOSCNT) matches with the active position-compare register (QPOSCMP) and the position-compare sync output of the programmable pulse width is generated on compare match to trigger an external device.

For example, if QPOSCMP = 2, the position-compare unit generates a position-compare event on 1 to 2 transitions of the eQEP position counter for forward counting direction and on 3 to 2 transitions of the eQEP position counter for reverse counting direction (see Figure 14-107).

Figure 14-129 shows the layout of the eQEP Position-Compare Control Register (QPOSCTL) and Table 14-101 describes the QPOSCTL bit fields.

Figure 14-107. eQEP Position-compare Event Generation Points

The pulse stretcher logic in the position-compare unit generates a programmable position-compare sync pulse output on the position-compare match. In the event of a new position-compare match while a previous position-compare pulse is still active, then the pulse stretcher generates a pulse of specified duration from the new position-compare event as shown in Figure 14-108.

Figure 14-108. eQEP Position-compare Sync Output Pulse Stretcher

14.4.2.5 eQEP Edge Capture Unit

The eQEP peripheral includes an integrated edge capture unit to measure the elapsed time between the unit position events as shown in Figure 14-109. This feature is typically used for low speed measurement using the following equation:

$$v(k) = \frac{X}{t(k) - t(k-1)} = \frac{X}{\Delta T} \quad (3)$$

where,

- X - Unit position is defined by integer multiple of quadrature edges (see Figure 14-110)
- ΔT - Elapsed time between unit position events
- v(k) - Velocity at time instant "k"

The eQEP capture timer (QCTMR) runs from prescaled SYSCLKOUT and the prescaler is programmed by the QCAPCTL[CCPS] bits. The capture timer (QCTMR) value is latched into the capture period register (QCPRD) on every unit position event and then the capture timer is reset, a flag is set in QEPSTS[UPEVNT] to indicate that new value is latched into the QCPRD register. Software can check this status flag before reading the period register for low speed measurement and clear the flag by writing 1.

Time measurement (ΔT) between unit position events will be correct if the following conditions are met:

- No more than 65,535 counts have occurred between unit position events.
- No direction change between unit position events.

The capture unit sets the eQEP overflow error flag (QEPSTS[COEF]) in the event of capture timer overflow between unit position events. If a direction change occurs between the unit position events, then an error flag is set in the status register (QEPSTS[CDEF]).

Capture Timer (QCTMR) and Capture period register (QCPRD) can be configured to latch on following events.

- CPU read of QPOSCNT register
- Unit time-out event

If the QEPCTL[QCLM] bit is cleared, then the capture timer and capture period values are latched into the QCTMRLAT and QCPRDLAT registers, respectively, when the CPU reads the position counter (QPOSCNT).

If the QEPCTL[QCLM] bit is set, then the position counter, capture timer, and capture period values are latched into the QPOSLAT, QCTMRLAT and QCPRDLAT registers, respectively, on unit time out.

Figure 14-111 shows the capture unit operation along with the position counter.

NOTE: The QCAPCTL register should not be modified dynamically (such as switching CAPCLK prescaling mode from QCLK/4 to QCLK/8). The capture unit must be disabled before changing the prescaler.

Figure 14-111. eQEP Edge Capture Unit - Timing Details

Velocity Calculation Equations:

$$v(k) = \frac{x(k) - x(k-1)}{T} = \frac{\Delta X}{T} \text{ o} \quad (4)$$

where

v(k): Velocity at time instant k

x(k): Position at time instant k

x(k-1): Position at time instant k - 1

T: Fixed unit time or inverse of velocity calculation rate

ΔX: Incremental position movement in unit time

X: Fixed unit position

ΔT: Incremental time elapsed for unit position movement

t(k): Time instant "k"

t(k-1): Time instant "k - 1"

Unit time (T) and unit period (X) are configured using the QUPRD and QCAPCTL[UPPS] registers. Incremental position output and incremental time output is available in the QPOSLAT and QCPRDLAT registers.

T	Unit Period Register (QUPRD)
ΔX	Incremental Position = QPOSLAT(k) - QPOSLAT(K - 1)
X	Fixed unit position defined by sensor resolution and ZCAPCTL[UPPS] bits
ΔT	Capture Period Latch (QCPRDLAT)

14.4.2.6 eQEP Watchdog

The eQEP peripheral contains a 16-bit watchdog timer that monitors the quadrature-clock to indicate proper operation of the motion-control system. The eQEP watchdog timer is clocked from SYSCLKOUT/64 and the quadrate clock event (pulse) resets the watchdog timer. If no quadrature-clock event is detected until a period match (QWDPRD = QWDTMR), then the watchdog timer will time out and the watchdog interrupt flag will be set (QFLG[WTO]). The time-out value is programmable through the watchdog period register (QWDPRD).

Figure 14-112. eQEP Watchdog Timer

14.4.2.7 Unit Timer Base

The eQEP peripheral includes a 32-bit timer (QUTMR) that is clocked by SYSCLKOUT to generate periodic interrupts for velocity calculations. The unit time out interrupt is set (QFLG[UTO]) when the unit timer (QUTMR) matches the unit period register (QUPRD).

The eQEP peripheral can be configured to latch the position counter, capture timer, and capture period values on a unit time out event so that latched values are used for velocity calculation as described in Section Section 14.4.2.5.

Figure 14-113. eQEP Unit Time Base

14.4.2.8 eQEP Interrupt Structure

Figure 14-114 shows how the interrupt mechanism works in the EQEP module.

Figure 14-114. EQEP Interrupt Generation

Eleven interrupt events (PCE, PHE, QDC, WTO, PCU, PCO, PCR, PCM, SEL, IEL, and UTO) can be generated. The interrupt control register (QEINT) is used to enable/disable individual interrupt event sources. The interrupt flag register (QFLG) indicates if any interrupt event has been latched and contains the global interrupt flag bit (INT). An interrupt pulse is generated only to the interrupt controller if any of the interrupt events is enabled, the flag bit is 1 and the INT flag bit is 0. The interrupt service routine will need to clear the global interrupt flag bit and the serviced event, via the interrupt clear register (QCLR), before any other interrupt pulses are generated. You can force an interrupt event by way of the interrupt force register (QFRC), which is useful for test purposes.

Table 14-99. eQEP Control Register (QEPCTL) Field Descriptions

Bits	Name	Value	Description
15-14	FREE, SOFT	0-3h	Emulation Control Bits
			QPOSCNT behavior:
		0	Position counter stops immediately on emulation suspend.
		1h	Position counter continues to count until the rollover.
		2h-3h	Position counter is unaffected by emulation suspend.
			QWDTMR behavior:
		0	Watchdog counter stops immediately.
		1	Watchdog counter counts until WD period match roll over.
		2h-3h	Watchdog counter is unaffected by emulation suspend.
			QUTMR behavior:
		0	Unit timer stops immediately.
		1h	Unit timer counts until period rollover.
		2h-3h	Unit timer is unaffected by emulation suspend.
			QCTMR behavior:
		0	Capture Timer stops immediately.
		1h	Capture Timer counts until next unit period event.
		2h-3h	Capture Timer is unaffected by emulation suspend.
13-12	PCRM	0-3h	Position counter reset mode
		0	Position counter reset on an index event
		1h	Position counter reset on the maximum position
		2h	Position counter reset on the first index event
		3h	Position counter reset on a unit time event
11-10	SEI	0-3h	Strobe event initialization of position counter
		0	Does nothing (action disabled)
		1h	Does nothing (action disabled)
		2h	Initializes the position counter on rising edge of the QEPS signal
		3h	**Clockwise Direction:** Initializes the position counter on the rising edge of QEPS strobe
			Counter Clockwise Direction: Initializes the position counter on the falling edge of QEPS strobe
9-8	IEI	0-3h	Index event initialization of position counter
		0	Do nothing (action disabled)
		1h	Do nothing (action disabled)
		2h	Initializes the position counter on the rising edge of the QEPI signal (QPOSCNT = QPOSINIT)
		3h	Initializes the position counter on the falling edge of QEPI signal (QPOSCNT = QPOSINIT)
7	SWI		Software initialization of position counter
		0	Do nothing (action disabled)
		1	Initialize position counter, this bit is cleared automatically

Table 14-99. eQEP Control Register (QEPCTL) Field Descriptions (continued)

Bits	Name	Value	Description
6	SEL		Strobe event latch of position counter
		0	The position counter is latched on the rising edge of QEPS strobe (QPOSSLAT = POSCCNT). Latching on the falling edge can be done by inverting the strobe input using the QSP bit in the QDECCTL register.
		1	**Clockwise Direction:** Position counter is latched on rising edge of QEPS strobe
			Counter Clockwise Direction: Position counter is latched on falling edge of QEPS strobe
5-4	IEL	0-3h	Index event latch of position counter (software index marker)
		0	Reserved
		1h	Latches position counter on rising edge of the index signal
		2h	Latches position counter on falling edge of the index signal
		3h	Software index marker. Latches the position counter and quadrature direction flag on index event marker. The position counter is latched to the QPOSILAT register and the direction flag is latched in the QEPSTS[QDLF] bit. This mode is useful for software index marking.
3	PHEN		Quadrature position counter enable/software reset
		0	Reset the eQEP peripheral internal operating flags/read-only registers. Control/configuration registers are not disturbed by a software reset.
		1	eQEP position counter is enabled
2	QCLM		eQEP capture latch mode
		0	Latch on position counter read by CPU. Capture timer and capture period values are latched into QCTMRLAT and QCPRDLAT registers when CPU reads the QPOSCNT register.
		1	Latch on unit time out. Position counter, capture timer and capture period values are latched into QPOSLAT, QCTMRLAT and QCPRDLAT registers on unit time out.
1	UTE		eQEP unit timer enable
		0	Disable eQEP unit timer
		1	Enable unit timer
0	WDE		eQEP watchdog enable
		0	Disable the eQEP watchdog timer
		1	Enable the eQEP watchdog timer

15.1 Introduction

The USB controller provides a low-cost connectivity solution for numerous consumer portable devices by providing a mechanism for data transfer between USB devices with a line/bus speed up to 480 Mbps. The device USB subsystem has two independent USB 2.0 Modules built around two OTG controllers. The OTG supplement feature, the support for a dynamic role change, is also supported. Each port has the support for a dual-role feature allowing for additional versatility enabling operation capability as a host or peripheral. Both ports have identical capabilities and operate independent of each other.

Each USB controller is built around the Mentor USB OTG controller (musbmhdrc) and TI GS70 PHY. Each USB controller has user configurable 32K Bytes of Endpoint FIFO and has the support for 15 'Transmit' endpoints and 15 'Receive' endpoints in addition to Endpoint 0. The USB subsystem makes use of the CPPI 4.1 DMA for accelerating data movement via a dedicated DMA hardware.

The two USB modules share the CPPI DMA controller and accompanying Queue Manager, Interrupt Pacer, Power Management module, and PHY/UTMI clock.

Within the descriptions of the USB subsystem that would follow, the term USB controller or USB PHY is used to mean/refer to any of the two USB controllers or PHYs existing within the USB subsystem. The term USB module is used to mean/refer to any of the two USB modules. USB0 is used to refer to one of the USB modules and USB1 is used to refer to the other USB module.

15.1.1 Acronyms, Abbreviations, and Definitions

AHB	Advanced High-performance Bus
CBA	Common Bus Architecture
CDC	Change Data Capture
CPPI	Communications Port Programming Interface
CPU	Central Processing Unit
DFT	Design for Test
DMA	Direct Memory Access
DV	Design Verification
EOI	End of Interrupt
EOP	End of Packet
FIFO	First-In First-Out
FS	Full-Speed USB data rate
HNP	Host Negotiation
HS	High-Speed USB data rate
INTD	Interrupt Distributor
IP	Intellectual Property
ISO	Isochronous transfer type
LS	Low-Speed USB data rate
MHz	Megahertz
MOP	Middle of Packet
OCP	Open Core Protocol
OCP HD	OCP High Performance
OCP MMR	OCP Memory Mapped Registers
OTG	On-The-Go
PDR	Physical Design Requirements
PHY	Physical Layer Device
PPU	Packet Processing Unit
RAM	Random Access Memory
RNDIS	Remote Network Driver Interface Specification

RX	Receive
SCR	Switched Central Resource
SOC	System On a Chip
SOP	Start of Packet
SRP	Session Resume
TX	Transmit
USB	Universal Serial Bus
USB0	One of the two USB 2.0 Compliant USB Module
USB1	One of the two USB2.0 Compliant USB Module
USBSS	USB Subsystem (contains USB0 and USB1)
UTMI	USB 2.0 Transceiver Macrocell Interface
XDMA	Transfer DMA (DMA other than CPPI DMA used within the Controller)

15.1.1.1 USB Features

The main features of the USB subsystem are:

- Contains 2 usb20otg_f controller modules with the following features:
  - Built around the Mentor USB 2.0 OTG core (musbmhdrc)
  - Supports USB 2.0 peripheral at speeds HS (480 Mb/s) and FS (12 Mb/s)
  - Supports USB 2.0 host or OTG at speeds HS (480 Mb/s), FS (12 Mb/s), and LS (1.5 Mb/s)
  - Supports all modes of transfers (control, bulk, interrupt, and isochronous)
  - Supports high bandwidth ISO mode
  - Supports 16 Transmit (TX) and 16 Receive (RX) endpoints including endpoint 0
  - Supports USB OTG extensions for Session Resume (SRP) and Host Negotiation (HNP)
  - Includes a 32K endpoint FIFO RAM, and supports programmable FIFO sizes
  - Includes RNDIS mode for accelerating RNDIS type protocols using short packet termination over USB
  - Includes CDC Linux mode for accelerating CDC type protocols using short packet termination over USB
  - Includes an RNDIS like mode for terminating RNDIS type protocols without using short packet termination for support of MSC applications
- Includes 2 GS70 USB2.0 OTG PHYs in C014.M process
- Interfaces to the CPU via 3 OCP interfaces:
  - Master OCP HP interface for the DMA
  - Master OCP HP interface for the Queue manager
  - Slave OCP MMR interface
- Includes a CPPI 4.1 compliant DMA controller sub-module with 30 RX and 30 TX simultaneous data connections
- Includes a CPPI 4.1 DMA scheduler
- DMA supports CPPI host descriptor formats
- DMA supports stall on buffer starvation
- Supports data buffer sizes up to 4M bytes
- CPPI FIFO interface per TX/RX endpoint
- Provides a CPPI Queue Manager module with 92 queues for queuing/de-queuing packets.
- DMA pacing logic for interrupts
- Loopback MGC test using the UTMI interfaces

15.2 Integration

This device implements the USB2.0 OTG dual port module and PHY for interfacing to USB as a peripheral or host.

Figure 15-1 shows the integration of the USB module on this device.

Figure 15-1. USB Integration

15.2.1 USB Connectivity Attributes

The USB module itself has a very large number of interrupt outputs. For ease of integration, these outputs are all routed to a pair of interrupt aggregators. These aggregator blocks generate a single interrupt on the first occurrence of any interrupt from the USB or DMA logic of the module.

Table 15-1. USB Connectivity Attributes

Attributes	Type
Power domain	Peripheral Domain
Clock domain	PD_PER_L3S_GCLK (OCP) CLKDCOLDO (PHY)
Reset signals	DEF_DOM_RST_N USB_POR_N
Idle/Wakeup signals	Smart idle Wakeup
Interrupt request	4 interrupts usbss to MPU subsystem usb0 to MPU subsystem usb1 to MPU subsystem slv0p_Swakeup to MPU subsystem and WakeM3 2 Wakeup Events to WakeM3 usb0_wuout usb1_wuout
DMA request	None
Physical address	L3 Slow slave port

15.2.2 USB Clock and Reset Management

Each USB controller has a PHY module that generates the UTMI clock. The UTMI clock is fixed in the UTMI specification for an 8-bit interface at 60 MHz (480 Mb/s). The PHYs require a low-jitter 960-MHz source clock.

Table 15-2. USB Clock Signals

Clock Signal	Max Freq	Reference / Source	Comments
ocp_clk OCP / Functional clock	100 MHz	CORE_CLKOUTM4 / 2	pd_per_l3s_gclk From PRCM
phy0_other_refclk960m Phy reference clock	960 MHz	CLKDCOLDO	clkdcoldo_po From Per PLL
phy1_other_refclk960m Phy reference clock	960 MHz	CLKDCOLDO	clkdcoldo_po From Per PLL

15.2.3 USB Pin List

The USB external interface signals are shown in Table 15-3.

Table 15-3. USB Pin List

Pin	Type*	Description
USBx_DP USBx_DM	I/O	USBx data differential pair
USBx_DRVVBUS	O	USBx VBUS supply control
USBx_VBUS	I	USBx VBUS (input only for voltage sensing)
USBx_ID	I	USBx OTG identification
USBx_CE	O	USBx Phy charge enable

15.2.4 USB GPIO Details

The USB module supports configuration of the DP and DM pins as pass-through GPIOs. In this device, the GPIO mode is used to provide UART over USB interface functionality. Chip level logic allows connection of the UART TX/RX data signals to either DP or DM in either normal or inverted state as shown in Figure 15-2. The diagram shows the UART2 / USB0 port implementation. This logic is also replicated for the UART3 / USB1 ports.

Figure 15-2. USB GPIO Integration

15.2.5 USB Unbonded PHY Pads

The USBOTGSS includes two USB PHY modules. On packages where only 1 PHY is bonded out to pins (e.g. 13x13 package), the following procedures must be followed in order to ensure that the unbonded PHY pads do not cause issues with USBOTGSS operation:

- The USB Controller corresponding to the unbonded PHY must be placed in Host Mode by setting Bit2 of the USB Core DEVCTL register.
- The unbonded PHY must be placed in the SUSPEND state by setting Bits[1:0] of the USB Core POWER register.
- The Control Module USB_CTRLx register corresponding to the unbonded PHY must have the following bits programmed as shown:
  - CHGDET_DIS = 1
  - CM_PWRDN = 1
  - GPIOMODE = 0

15.3 Functional Description

The USB controller within the device supports 15 Transmit endpoints and 15 Receive endpoints in addition to Endpoint 0. (The use of these endpoints for IN and OUT transactions depends on whether the USB controller is being used as a device/peripheral or as a host. When used as a peripheral, IN transactions are processed through TX endpoints and OUT transactions are processed through Rx endpoints. When used as a host, IN transactions is processed through Rx endpoints and OUT transactions is processed through TX endpoints.)

These additional endpoints can be individually configured in software to handle either Bulk transfers (which also allows them to handle Interrupt transfers), Isochronous transfers or Control transfers. Further, the endpoints can also be allocated to different target device functions on the fly – maximizing the number of devices that can be simultaneously supported.

Each endpoint requires a chunk of memory allocated within the FIFO to be associated with it. The USB module has a single block of FIFO RAM (32 Kbytes in size) to be shared by all endpoints. The FIFO for Endpoint 0 is required to be 64 bytes deep and will buffer 1 packet. The first 64 Bytes of the FIFO RAM is reserved by hardware for Endpoint 0 usage and for this reason user software does not need (nor has the capability) to allocate FIFO for Endpoint 0. The rest of the FIFO RAM is user configurable with regard to the other endpoint FIFOs, which may be from 8 to 8192 bytes in size and can buffer either 1 or 2 packets.

Separate FIFOs may be associated with each endpoint: alternatively a TX endpoint and the Rx endpoint with the same Endpoint number can be configured to use the same FIFO, for example to reduce the size of RAM block needed, provided they can never be active at the same time.

The role (host or device) that the USB controller assumes is chosen by user firmware programming the respective USB controller MODE register defined within the USB subsystem space. Note that some USB pins have not been bonded out and the functions of these pins are controlled by user software via dedicated registers.

The user has access to the controller through the OCP slave interface via the CPU. The user can process USB transactions entirely from the CPU or can also use the DMA to perform data transfer. The CPPI DMA can be used to service Endpoints 1 to 15 not Endpoint 0. CPU access method is used to service Endpoint 0 transactions.

15.3.1 VBUS Voltage Sourcing Control

When any of the USB controllers assumes the role of a host, the USB is required to supply a 5V power source to an attached device through its VBUS line. In order to achieve this task, the USB controller requires the use of an external power logic (or charge pump) capable of sourcing 5V power. A USB_DRVVBUS is used as a control signal to enable/disable this external power logic to either source or disable power on the VBUS line. The control on the USB_DRVVBUS is automatic and is handled by the USB controller. The control should be transparent to the user so long as the proper hardware connection and software initialization are in place. The USB controller drives the USB_DRVVBUS signal high when it assumes the role of a host while the controller is in session. When assuming the role of a device, the controller drives the USB_DRVVBUS signal low disabling the external charge pump/power logic; hence, no power is driven on the VBUS line (in this case, power is expected to be sourced by the external host).

Note that both USBs are self-powered and the device does not rely on the voltage on the VBUS line sourced by an external host for controller operation when assuming the role of a device. The power on the VBUS is used to identify the presence of a Host. It is also used to power up the pull-up on the D+ line. The USB PHY would continually monitor the voltage on the VBUS and report the status to USB controller.

15.3.2 Pull-up/Pull-Down Resistors

Since the USB controllers are dual role controllers, capable of assuming a role of a host or device, the necessary required pull-up/pull-down resistors can not exist external to the device. These pull-up/pull-down resistors exist internal to the device, within the PHY to be more specific, and are enabled and disabled based on the role the controller assumes allowing dynamic hardware configuration.

When assuming the role of a host, the data lines are pulled low by the PHY enabling the internal 15KOhms resistors. When assuming the role of a device the required 1.5Kohm pull-up resistor on the D+ line is enabled automatically to signify the USB capability to the external host as a FS device (HS operation is negotiated during reset bus condition).

Copyright © 2011, Texas Instruments Incorporated

15.3.3 Role Assuming Method

For an OTG controller, the usual method followed by the controller to assume the role of a host or a device is governed by the state of the ID pin which in turn is controlled by the USB cable connector type. The DM814x device has bonded out these ID pins and allows the control to be handled directly from the connector, i.e. the USB controller would assume the role based on the cable end inserted to the mini or micro A/B connector. An alternate method where the ID pin signal is bypassed and the firmware controls the role the controller assumes exists via register access allowing additional control for systems that do not require the use of the USB ID pin. In this case the USBnMODE [Bit7=IDDIG_MUX] needs to be programmed with a value of 1 so that Register programming will be used.

Two registers, USB0 Mode Register at offset 10E8h and USB1 Mode Register at offset 18E8h, are used for a user to select the role the USB controller assumes. The user is required to program the corresponding register prior to the USB controller is in session.

15.3.4 Clock, PLL, and PHY Initialization

Prior to configuring the USB Module Registers, the DM814x USB SubSystem and PHY are required to be released from reset, enable interconnects and controllers clocks as well as configure the USB PHY with appropriate setting. Not all registers related for this task are captured within this document. Please refer to the PRCM for clocking and Control Module for PHY configuration registers definitions.

Note: The following initialization makes use of the s/w option where USB role is controlled by firmware programming USBx Mode Register.

Clock Related Configuration:

```
*0x48180B10 &= 0xFFFFFF9F; // RSTCTRL (Release USB Module from Reset)
while ((0x48180B14 & 0x00000060)>>5)!=0x3); // Wait until Modules come out Reset
*0x48180B14 |= 0x00000060; // RSTST (Clear Reset Presence)
*0x48180514 = 0x2; // L3_SLOW_CLKSTCTRL (Enable Interconnect Clock)
*0x48180558 = 0x2; // USB_CLKCTRL (Enable USB OCP Clock)
while(((*0x48180558) & 0x70000)>>16)==0x7); // Wait until USB Module is Ready
```

USB PLL Related:

```
PLL_SUBSYS_BASE  =  0x481C5000
USB_PLL_BASE  =  PLL_SUBSYS_BASE + 0x260
Output clock frequency from PLL (according to above function call) = (((OSC
frequency/(N+1))*M)/M2) = (((20MHz/(19+1))*960)/1) = 960MHz

*(0x481C5270) = 0x00010013; // USB_PLLM2NDIV
*(0x481C5274)  = 0x000003C0; // USB_PLLMN2DIV

/* Load M2, N2 dividers of ADPLL */
*(0x481C526C) = 0x00000001; // USBPLL_TENABLEDIV
   // Toggle to Complete Load
*(0x481C526C) = 0x00000000; // USBPLL_TENABLEDIV

/* Load M, N dividers of ADPLL */
*(0x481C5268) = 0x00000001; // USBPLL_TENABLE
   // Toggle to Complete Load
*(0x481C5268) = 0x00000000; // USBPLL_TENABLE

*(0x481C5264) = ((*(0x481C5264) & 0xff7fe3ff) | 0x200a080a); // USBPLL_CLKCTRL
/* Wait for phase and freq lock */
while (((*(0x481C5284)) & 0x00000600) != 0x00000600); // USBPLL_STATUS
```

USB PHY Related

```
// Clear bits 0,1,8,9,15,16,23
*(48140620) & = ~(0x00818303); // USB_CTRL0
// Set bits 6,7,10,13,14,17,18,19,20
*(48140620)  |= 0x001E64C0;    // USB_CTRL0
```

Firmware is now ready to continue programming the USB Controllers.

15.3.5 Indexed and Non-Indexed Register Spaces

The USB controller provides two mechanisms for accessing endpoint control and status registers; Indexed and Non-Indexed method.

Indexed Endpoint Control/Status Register Space. This register space can be thought of as a region populated with Proxy Registers. This register space is a memory-mapped region at offset 1410h to 141Fh for USB0 and 1C10h to 1C1Fh for USB1. The endpoint register space mapped at this region is selected by programming the corresponding INDEX register (@ offsets 140Eh and 1C0Eh for USB0 and USB1 respectively) of the controller.

By programming the INDEX register with the corresponding endpoint number, the control and status register corresponding to that particular endpoint is accessible from this Indexed Region. In other words, Index Register region behaves as a proxy to access a selected endpoint registers.

Non-indexed Endpoint Control/Status Register Space. These regions are dedicated endpoint registers memory-mapped residing at offsets 1500h to 16FFh for USB0 and 1D00h to 1EFFh for USB1. Registers at offset 1500h to 150Fh belong to Endpoint 0; registers at offset 1510h to 151Fh belong to Endpoint 1… and lastly registers at offset 16F0h to 16FFh belong to Endpoint 15 for USB0. Similarly registers at offset 1D00h to 1E0Fh belong to Endpoint 0; registers at offset 1D10h to 1D1Fh belong to Endpoint 1… and finally registers at offset 1DF0h to 1DFFh belong to Endpoint 15 for USB1.

This allows the user/firmware to access an endpoint register region directly from its unique space, as specified within a non-indexed region or from a proxy space by programming the corresponding Index register.

Note: The control and status registers/regions apply to both Tx and Rx of a given Endpoint. That is, Endpoint 1 Tx and Endpoint 1 Rx registers occupy the same register space.

For detailed information about the USB controller registers, see Section 15.5.2.

15.3.6 Dynamic FIFO Sizing

Each USB module supports a total of 32K bytes of FIFO RAM to dynamically allocate FIFO to all endpoints in use. Each endpoint requires a FIFO to be associated with it. There is one set of register per endpoint available for FIFO allocation, excluding endpoint 0. FIFO configuration registers are Indexed registers and cannot be accessed directly; configuration takes place via accessing proxy registers. The INDEX register at addresses 140Eh or 1C0Eh must be set to the appropriate endpoint. In other words, the Endpoint FIFO configuration registers do not have non-indexed regions.

The allocation of FIFO space to the different endpoints requires programming for each Tx and Rx endpoint with the following information:

- The start address of the FIFO within the RAM block
- The maximum size of packet to be supported
- Whether double-buffering is required

(These last two together define the amount of space that needs to be allocated to the FIFO.)

It is the responsibility of the firmware to ensure that all the Tx and Rx endpoints (other than endpoint 0) that are active in the current USB configuration have a block of FIFO RAM allocated for their use. The maximum FIFO size for endpoint 0 required is 64 bytes deep and which is large enough to buffer one packet. For this reason, the first 64 bytes of FIFO memory is reserved for Endpoint 0 usage and this resource allocation is implied to be available at all times and no FIFO allocation is required for Endpoint 0. For endpoints other than endpoint 0, the FIFO RAM interface is configurable and must have a minimum size of 8 bytes and should be capable of buffering either 1 or 2 packets. Separate FIFOs may be associated with each endpoint: alternatively a Tx endpoint and the Rx endpoint with the same Endpoint number can be configured to use the same FIFO, to reduce the size of RAM block needed, provided they can never be active at the same time.

NOTE: The option of dynamically setting FIFO sizes only applies to Endpoints 1-15. Endpoint 0 FIFO has a fixed size (64 bytes) and a fixed location which is the first 64 Bytes of FIFO (FIFO addresses 0-63).

Copyright © 2011, Texas Instruments Incorporated

15.3.7 USB Controller Host and Peripheral Modes Operation

The two USB modules can be used in a range of different environments. They can be used as either a high-speed or a full-speed USB peripheral device attached to a conventional USB host (such as a PC) in a point-to-point type of arrangement. As a host, the USB modules can also be used with another peripheral device of any speed (high-,full-, or low-speed) in a point-to-point arrangement or can be used as the host to a range of peripheral devices in a multi-point setup; one-to-many via hub. Note that the role each USB controller is assuming is independent of each other. Two options (h/w or s/w) exist for a USB role assumption/configuration.

For a USB Peripheral configuration the user has the option of using the cable end to select the role by attaching the mini or micro b side of the cable (can consider this as a h/w option) or use the optional method where the firmware is required to program the respective USB Mode Register IDDIG bit field with a value of ‘1’ prior to the USB controller goes into session (can consider this as a s/w option).

Similarly, for a USB host configuration the user has the option of using the cable end to select the role by attaching the mini or micro a side of the cable (can consider this as a h/w option) or use the optional method where the firmware is required to program the respective USB Mode Register IDDIG bit field with a value of ‘0’ value prior to the USB controller going into session (can consider this as a s/w option).

When using the s/w option, the USB ID pin state is ignored/bypassed (this is a similar configuration where an ID pin does not exist) and the USB2.0 controller role adaptation of a host or peripheral (device) is dependent upon the state of the respective USB Mode Register IDDIG field. If the IDDIG field is programmed by the user with a value of ‘1’ prior to the USB going into session, it would assume the role of a peripheral/device. However, if the IDDIG field is programmed with the value of ‘0’, the USB controller will assume the role of a host. What this means is that the USB cable end, connector, will not be able to control the role of the OTG controller and the user needs to be aware of the firmware program setting prior to performing a USB connection.

The procedure for the USB2.0 OTG controller determining its operating modes (usb controller assuming a role of a host or a peripheral) starts when the USB 2.0 controller goes into a session. The USB 2.0 controller is in session when either it senses a voltage (>= 4.4V) on the USBx_VBUSIN pin and the controller sets its DEVCTL[SESSION] bit field or when the firmware sets the DEVCTL[SESSION] bit; assuming that it will operating as a host.

When the DEVCTL[SESSION] bit is set, the controller will start sensing the state of the Iddig signal, which in turn is controlled either by the USBx_ID pin (h/w option) or by the IDDIG bit field of the MODE Register (s/w option). If the state of the iddig signal is found to be low (IDDIG is programmed with ‘0’) then the USB2.0 controller will assume the role of a host and when it finds the iddig signal to be high (IDDIG is programmed with ‘1’) then it will assume the role of a device. Note that iddig is an internal signal that could be driven to high or low via firmware from dedicated registers.

Upon the USB controller determining its role as a host, it will drive the USBx_DRVVBUS pin high to enable the external power logic so that it start sourcing the required 5V power (must be ≥ 4.4V but to account for the voltage drop on the cable it is suggested to be in the neighborhood of 4.75V). The USB2.0 controller will then wait to for the voltage of the USBx_VBUSIN to go high. Upon sampling a little time later, if it does not see the voltage on the USBX_VBUSIN pin to be within a Vbus Valid range (>= 4.4V), it will generate a Vbus error interrupt. Assuming that the voltage level of the USBX_VBUSIN is found to within the Vbus Valid range, the USB 2.0 host controller will wait for a device to connect; that is for it to see one of its data lines USB0/1_DP/DM be pulled high.

When assuming the role of a peripheral, assuming that the firmware has set the POWER[SOFTCONN] bit, and the USBx_ID pin is floating (h/w option) or USBx Mode Register IDDIG bit field is programmed with ‘1’ (s/w option) and an external host is sourcing power on the USBx_VBUSIN line then the USB2.0 controller will set the DEVCTL[SESSION] bit instructing the controller to go into session. Not that the voltage on the USBx_VBUSIN pin must be within Vbus Valid range (i.e. greater or equal to 4.4V). When the controller goes into session, it will force the USB2.0 Controller to sense the state of the iddig signal. Once it senses iddig signal to be high, it will enable its 1.5Kohm pull-up resistor to signify the external host that it is a Full-Speed device. Note that even when operating as a High-Speed peripheral; the USB controller has to first come up as Full-Speed and then later transition to High-Speed. The USB2.0 controller will then waits for a reset signal from the external host. Then after, if High-Speed option has been selected it will negotiate for a High-Speed operation and if its request has been accepted by the host, it will enable its precision 45ohm termination resistors (to stop signal reflection) on its data lines and disable the 1.5Kohm resistor.

15.3.8 Protocol Description(s)

This section describes the implementation of the USB protocol(s) by the USB modules.

15.3.8.1 USB Controller Peripheral Mode Operation

The USB controller assumes the role of a peripheral when the USBx_ID pin is floating or USB Mode Register[iddig=bit8] is set to 1 (provided that iddig_mux, which is bit7 of USBnMODE is also set to 1) by the user application prior to the controller goes into session. When the USB controller go into session it will assume the role of a device.

Soft connect –After a POR or USB Module soft reset, the SOFTCONN bit of POWER register (bit 6) is cleared to 0. The controller will therefore appear disconnected until the software has set the SOFTCONN bit to 1. The application software can then choose when to set the PHY into its normal mode. Systems with a lengthy initialization procedure may use this to ensure that initialization is complete and the system is ready to perform enumeration before connecting to the USB. Once the SOFTCONN bit has been set, the software can also simulate a disconnect by clearing this bit to 0.

Entry into suspend mode –When operating as a peripheral device, the controller monitors activity on the bus and when no activity has occurred for 3 ms, it goes into Suspend mode. If the Suspend interrupt has been enabled, an interrupt will be generated at this time.

At this point, the controller can then be left active (and hence able to detect when Resume signaling occurs on the USB), or the application may arrange to disable the controller by stopping its clock. However, the controller will not then be able to detect Resume signaling on the USB if clocks are not running. If such is the case, external hardware will be needed to detect Resume signaling (by monitoring the DM and DP signals), so that the clock to the controller can be restarted.

Resume Signaling –When resume signaling occurs on the bus, first the clock to the controller must be restarted if necessary. Then the controller will automatically exit Suspend mode. If the Resume interrupt is enabled, an interrupt will be generated.

Initiating a remote wakeup –If the software wants to initiate a remote wakeup while the controller is in Suspend mode, it should set the POWER[RESUME] bit to 1. The software should leave then this bit set for approximately 10 ms (minimum of 2 ms, a maximum of 15 ms) before resetting it to 0.

NOTE: No resume interrupt will be generated when the software initiates a remote wakeup.

Reset Signaling –When reset signaling or bus condition occurs on the bus, the controller performs the following actions:

- Clears FADDR register to 0
- Clears INDEX register to 0
- Flushes all endpoint FIFOs
- Clears all controller control/status registers
- Generates a reset interrupt
- Enables all interrupts at the core level.

If the HSENA bit within the POWER register (bit 5) is set, the controller also tries to negotiate for high-speed operation. Whether high-speed operation is selected is indicated by HSMODE bit of POWER register (bit 4). When the application software receives a reset interrupt, it should close any open pipes and wait for bus enumeration to begin.

15.3.8.1.1 Control Transactions:Peripheral Mode

Endpoint 0 is the main control endpoint of the core. The software is required to handle all the standard device requests that may be sent or received via endpoint 0. These are described in Universal Serial Bus Specification, Revision 2.0, Chapter 9. The protocol for these device requests involves different numbers and types of transactions per request/command. To accommodate this, the software needs to take a state machine approach to command decoding and handling.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

The Standard Device Requests received by a USB peripheral device can be divided into three categories: Zero Data Requests (in which all the information is included in the command; no additional data is required), Write Requests (in which the command will be followed by additional data), and Read Requests (in which the device is required to send data back to the host).

This section looks at the sequence of actions that the software must perform to process these different types of device request.

NOTE: The Setup packet associated with any standard device request should include an 8-byte command. Any setup packet containing a command field other than 8 bytes will be automatically rejected by the controller.

15.3.8.1.1.1 Zero Data Requests: Peripheral Mode

Zero data requests have all their information included in the 8-byte command and require no additional data to be transferred. Examples of Zero Data standard device requests are:

- SET_FEATURE
- CLEAR_FEATURE
- SET_ADDRESS
- SET_CONFIGURATION
- SET_INTERFACE

The sequence of events will begin, as with all requests, when the software receives an endpoint 0 interrupt. The RXPKTRDY bit of PERI_CSR0 (bit 0) will also have been set. The 8-byte command should then be read from the endpoint 0 FIFO, decoded and the appropriate action taken.

For example, if the command is SET_ADDRESS, the 7-bit address value contained in the command should be written to the FADDR register at the completion of the command. The PERI_CSR0 register should be written by setting the SERV_RXPKTRDY bit (bit 6) (indicating that the command has been read from the FIFO) and also setting the DATAEND bit (bit 3) (indicating that no further data is expected for this request). The interval between setting SERV_RXPKTRDY bit and DATAEND bit should be very small to avoid getting a SETUPEND error condition. It is highly recommended to set both bits at the same time.

When the host moves to the status stage of the request, a second endpoint 0 interrupt will be generated to indicate that the request has completed. No further action is required from the software. The second interrupt is just a confirmation that the request completed successfully. For SET_ADDRESS command, the address should be written to FADDR register at the completion of the command, i.e. when the status stage interrupt is received.

If the command is an unrecognized command, or for some other reason cannot be executed, then when it has been decoded, the PERI_CSR0 register should be written to set the SERV_RXPKTRDY bit (bit 6) and to set the SENDSTALL bit (bit 5). When the host moves to the status stage of the request, the controller will send a STALL packet telling the host that the request was not executed. A second endpoint 0 interrupt will be generated and the SENTSTALL bit (bit 2 of PERI_CSR0) will be set.

If the host sends more data after the DATAEND bit has been set, then the controller will send a STALL packet automatically. An endpoint 0 interrupt will be generated and the SENTSTALL bit (bit 2 of PERI_CSR0) will be set.

NOTE: DMA is not supported for endpoint 0; endpoint 0 is always serviced via CPU.

15.3.8.1.1.2 Write Requests: Peripheral Mode

Write requests involve an additional packet (or packets) of data being sent from the host after the 8-byte command. An example of a Write standard device request is: SET_DESCRIPTOR.

The sequence of events will begin, as with all requests, when the software receives an endpoint 0 interrupt. The RXPKTRDY bit of PERI_CSR0 will also have been set. The 8-byte command should then be read from the Endpoint 0 FIFO and decoded.

As with a zero data request, the PERI_CSR0 register should then be written to set the SERV_RXPKTRDY bit (bit 6) (indicating that the command has been read from the FIFO) but in this case the DATAEND bit (bit 3) should not be set (indicating that more data is expected).

Copyright © 2011, Texas Instruments Incorporated

When a second endpoint 0 interrupt is received, the PERI_CSR0 register should be read to check the endpoint status. The RXPKTRDY bit of PERI_CSR0 should be set to indicate that a data packet has been received. The COUNT0 register should then be read to determine the size of this data packet. The data packet can then be read from the endpoint 0 FIFO.

If the length of the data associated with the request (indicated by the wLength field in the command) is greater than the maximum packet size for endpoint 0, further data packets will be sent. In this case, PERI_CSR0 should be written to set the SERV_RXPKTRDY bit, but the DATAEND bit should not be set.

When all the expected data packets have been received, the PERI_CSR0 register should be written to set the SERV_RXPKTRDY bit and to set the DATAEND bit (indicating that no more data is expected).

When the host moves to the status stage of the request, another endpoint 0 interrupt will be generated to indicate that the request has completed. No further action is required from the software, the interrupt is just a confirmation that the request completed successfully.

If the command is an unrecognized command, or for some other reason cannot be executed, then when it has been decoded, the PERI_CSR0 register should be written to set the SERV_RXPKTRDY bit (bit 6) and to set the SENDSTALL bit (bit 5). When the host sends more data, the controller will send a STALL to tell the host that the request was not executed. An endpoint 0 interrupt will be generated and the SENTSTALL bit of PERI_CSR0 (bit 2) will be set.

If the host sends more data after the DATAEND has been set, then the controller will send a STALL. An endpoint 0 interrupt will be generated and the SENTSTALL bit of PERI_CSR0 (bit 2) will be set.

15.3.8.1.1.3 Read Requests: Peripheral Mode

Read requests have a packet (or packets) of data sent from the function to the host after the 8-byte command. Examples of Read Standard Device Requests are:

- GET_CONFIGURATION
- GET_INTERFACE
- GET_DESCRIPTOR
- GET_STATUS
- SYNCH_FRAME

The sequence of events will begin, as with all requests, when the software receives an endpoint 0 interrupt. The RXPKTRDY bit of PERI_CSR0 (bit 0) will also have been set. The 8-byte command should then be read from the endpoint 0 FIFO and decoded. The PERI_CSR0 register should then be written to set the SERV_RXPKTRDY bit (bit 6) (indicating that the command has read from the FIFO).

The data to be sent to the host should then be written to the endpoint 0 FIFO. If the data to be sent is greater than the maximum packet size for endpoint 0, only the maximum packet size should be written to the FIFO. The PERI_CSR0 register should then be written to set the TXPKTRDY bit (bit 1) (indicating that there is a packet in the FIFO to be sent). When the packet has been sent to the host, another endpoint 0 interrupt will be generated and the next data packet can be written to the FIFO.

When the last data packet has been written to the FIFO, the PERI_CSR0 register should be written to set the TXPKTRDY bit and to set the DATAEND bit (bit 3) (indicating that there is no more data after this packet).

When the host moves to the status stage of the request, another endpoint 0 interrupt will be generated to indicate that the request has completed. No further action is required from the software: the interrupt is just a confirmation that the request completed successfully.

If the command is an unrecognized command, or for some other reason cannot be executed, then when it has been decoded, the PERI_CSR0 register should be written to set the SERV_RXPKTRDY bit (bit 6) and to set the SENDSTALL bit (bit 5). When the host requests data, the controller will send a STALL to tell the host that the request was not executed. An endpoint 0 interrupt will be generated and the SENTSTALL bit of PERI_CSR0 (bit 2) will be set.

If the host requests more data after DATAEND (bit 3) has been set, then the controller will send a STALL. An endpoint 0 interrupt will be generated and the SENTSTALL bit of PERI_CSR0 (bit 2) will be set.

15.3.8.1.1.4 Endpoint 0 States: Peripheral Mode

When the USB controller is operating as a peripheral device, the endpoint 0 control needs three modes – IDLE, TX and RX – corresponding to the different phases of the control transfer and the states endpoint 0 enters for the different phases of the transfer (described in later sections).

The default mode on power-up or reset should be IDLE. RXPKTRDY bit of PERI_CSR0 (bit 0) becoming set when endpoint 0 is in IDLE state indicates a new device request. Once the device request is unloaded from the FIFO, the controller decodes the descriptor to find whether there is a data phase and, if so, the direction of the data phase of the control transfer (in order to set the FIFO direction). See Figure 15-3.

Depending on the direction of the data phase, endpoint 0 goes into either TX state or RX state. If there is no Data phase, endpoint 0 remains in IDLE state to accept the next device request

The actions that the CPU needs to take at the different phases of the possible transfers (for example, loading the FIFO, setting TXPKTRDY) are indicated in Figure 15-4.

15.3.8.1.1.4.1 Endpoint 0 Interrupt Generating Events: Peripheral Mode

An Endpoint 0 interrupt is generated when any of the below events occur and Interrupt Service handler should determine the right event and launch the proper handler

The following events will cause Endpoint 0 Interrupt to be generated while the controller is operating assuming the role of a device/peripheral:

- The controller sets the RXPKTRDY bit of PERI_CSR0 (bit 0) after a valid token has been received and data has been written to the FIFO (legal status condition).
- The controller clears the TXPKTRDY bit of PERI_CSR0 (bit 1) after the packet of data in the FIFO has been successfully transmitted to the host (legal status condition).
- The controller sets the SENTSTALL bit of PERI_CSR0 (bit 2) after a control transaction is ended due to a protocol violation (illegal status condition).
- The controller sets the SETUPEND bit of PERI_CSR0 (bit 4) because a control transfer has ended before DATAEND (bit 3 of PERI_CSR0) is set (illegal status condition).

In order to determine the cause of the interrupt, the detail below recommends the order of cause determination and execution.

Whenever the endpoint 0 service routine is entered, the software must first check to see if the current control transfer has been ended due to either a STALL condition or a premature end of control transfer. If the control transfer ends due to a STALL condition, the SENTSTALL bit would be set. If the control transfer ends due to a premature end of control transfer, the SETUPEND bit would be set. In either case, the software should abort processing the current control transfer and set the state to IDLE.

Once the software has determined that the interrupt was not generated by an illegal bus state, the next action taken depends on the endpoint state.

If endpoint 0 is in IDLE state, the only valid reason an interrupt can be generated is as a result of the controller receiving data from the bus. The service routine must check for this by testing the RXPKTRDY bit of PERI_CSR0 (bit 0). If this bit is set, then the controller has received a SETUP packet. This must be unloaded from the FIFO and decoded to determine the action the controller must take. Depending on the command contained within the SETUP packet, endpoint 0 will enter one of three states:

- If the command is a single packet transaction (SET_ADDRESS, SET_INTERFACE etc.) without any data phase, the endpoint will remain in IDLE state.
- If the command has an OUT data phase (SET_DESCRIPTOR etc.), the endpoint will enter RX state.
- If the command has an IN data phase (GET_DESCRIPTOR etc.), the endpoint will enter TX state.
- If the endpoint 0 is in TX state, the interrupt indicates that the core has received an IN token and data from the FIFO has been sent. The software must respond to this either by placing more data in the FIFO if the host is still expecting more data or by setting the DATAEND bit to indicate that the data phase is complete. Once the data phase of the transaction has been completed, endpoint 0 should be returned to IDLE state to await the next control transaction (status stage).
- If the endpoint is in RX state, the interrupt indicates that a data packet has been received. The software must respond by unloading the received data from the FIFO. The software must then determine whether it has received all of the expected data. If it has, the software should set the DATAEND bit and return endpoint 0 to IDLE state. If more data is expected, the firmware should set the SERV_RXPKTRDY bit of PERI_CSR0 (bit 6) to indicate that it has read the data in the FIFO and leave the endpoint in RX state.

15.3.8.1.1.4.2 Idle Mode: Control Transfer of Peripheral Mode

IDLE mode is the mode the Endpoint 0 control needs to select at power-on or reset and is the mode to which the Endpoint 0 control should return when the RX and TX modes are terminated.

It is also the mode in which the SETUP phase of control transfer is handled (as outlined in Figure 15-5).

Figure 15-5. Flow Chart of Setup Stage of a Control Transfer in Peripheral Mode

15.3.8.1.1.4.3 TX Mode: Control Transfer of Peripheral Mode

When the endpoint is in TX state, all arriving IN tokens need to be treated as part of a data phase until the required amount of data has been sent to the host. If either a SETUP or an OUT token is received while the endpoint is in the TX state, this will cause a SETUPEND condition to occur as the core expects only IN tokens.

Three events can cause TX mode to be terminated before the expected amount of data has been sent as shown in Figure 15-6:

1. The host sends an invalid token causing a SETUPEND condition (bit 4 of PERI_CSR0 is set).
2. The firmware sends a packet containing less than the maximum packet size for Endpoint 0.
3. The firmware sends an empty data packet.

Until the transaction is terminated, the firmware simply needs to load the FIFO when it receives an interrupt which indicates that a packet has been sent from the FIFO. An interrupt is generated when TXPKTRDY is cleared.

When the firmware forces the termination of a transfer (by sending a short or empty data packet), it should set the DATAEND bit of PERI_CSR0 (bit 3) to indicate to the core that the data phase is complete and that the core should next receive an acknowledge packet.

Figure 15-6. Flow Chart of Transmit Data Stage of a Control Transfer in Peripheral Mode

15.3.8.1.1.4.4 Rx Mode: Control Transfer of Peripheral Mode

In RX mode, all arriving data should be treated as part of a data phase until the expected amount of data has been received. If either a SETUP or an IN token is received while the endpoint is in RX state, a SETUPEND condition will occur as the controller expects only OUT tokens.

Three events can cause RX mode to be terminated before the expected amount of data has been received as shown in Figure 15-7:

1. The host sends an invalid token causing a SETUPEND condition (setting bit 4 of PERI_CSR0).
2. The host sends a packet which contains less than the maximum packet size for endpoint 0.
3. The host sends an empty data packet.

Until the transaction is terminated, the software unloads the FIFO when it receives an interrupt that indicates new data has arrived (setting RXPKTRDY bit of PERI_CSR0) and to clear RXPKTRDY by setting the SERV_RXPKTRDY bit of PERI_CSR0 (bit 6).

When the software detects the termination of a transfer (by receiving either the expected amount of data or an empty data packet), it should set the DATAEND bit (bit 3 of PERI_CSR0) to indicate to the controller that the data phase is complete and that the core should receive an acknowledge packet next.

15.3.8.1.1.4.5 Error Handling: Control Transfer of Peripheral Mode

A control transfer may be aborted due to a protocol error on the USB, the host prematurely ending the transfer, or if the software wishes to abort the transfer (for example, because it cannot process the command).

The controller automatically detects protocol errors and sends a STALL packet to the host under the following conditions:

- The host sends more data during the OUT Data phase of a write request than was specified in the command. This condition is detected when the host sends an OUT token after the DATAEND bit (bit 3 of PERI_CSR0) has been set.
- The host requests more data during the IN Data phase of a read request than was specified in the command. This condition is detected when the host sends an IN token after the DATAEND bit in the PERI_CSR0 register has been set.
- The host sends more than Max Packet Size data bytes in an OUT data packet.
- The host sends a non-zero length DATA1 packet during the STATUS phase of a read request.

When the controller has sent the STALL packet, it sets the SENTSTALL bit (bit 2 of PERI_CSR0) and generates an interrupt. When the software receives an endpoint 0 interrupt with the SENTSTALL bit set, it should abort the current transfer, clear the SENTSTALL bit, and return to the IDLE state.

If the host prematurely ends a transfer by entering the STATUS phase before all the data for the request has been transferred, or by sending a new SETUP packet before completing the current transfer, then the SETUPEND bit (bit 4 of PERI_CSR0) will be set and an endpoint 0 interrupt generated. When the software receives an endpoint 0 interrupt with the SETUPEND bit set, it should abort the current transfer, set the SERV_SETUPEND bit (bit 7 of PERI_CSR0), and return to the IDLE state. If the RXPKTRDY bit (bit 0 of PERI_CSR0) is set this indicates that the host has sent another SETUP packet and the software should then process this command.

If the software wants to abort the current transfer, because it cannot process the command or has some other internal error, then it should set the SENDSTALL bit (bit 5 of PERI_CSR0). The controller will then send a STALL packet to the host, set the SENTSTALL bit (bit 2 of PERI_CSR0) and generate an endpoint 0 interrupt.

15.3.8.1.1.5 Additional Conditions: Control Transfer of Peripheral Mode

When working as a peripheral device, the controller automatically responds to certain conditions on the USB bus or actions by the host. The details are:

- Stall Issued to Control Transfers
  1. The host sends more data during an OUT Data phase of a Control transfer than was specified in the device request during the SETUP phase. This condition is detected by the controller when the host sends an OUT token (instead of an IN token) after the software has unloaded the last OUT packet and set DATAEND.
  2. The host requests more data during an IN data phase of a Control transfer than was specified in the device request during the SETUP phase. This condition is detected by the controller when the host sends an IN token (instead of an OUT token) after the software has cleared TXPKTRDY and set DATAEND in response to the ACK issued by the host to what should have been the last packet.
  3. The host sends more than MaxPktSize data with an OUT data token.
  4. The host sends the wrong PID for the OUT Status phase of a Control transfer.
  5. The host sends more than a zero length data packet for the OUT Status phase.
- Zero Length Out Data Packets In Control Transfer
  A zero length OUT data packet is used to indicate the end of a Control transfer. In normal operation, such packets should only be received after the entire length of the device request has been transferred (i.e., after the software has set DataEnd). If, however, the host sends a zero length OUT data packet before the entire length of device request has been transferred, this signals the premature end of the transfer. In this case, the controller will automatically flush any IN token loaded by software ready for the Data phase from the FIFO and set SETUPEND bit (bit 4 of PERI_CSR0).

15.3.8.1.2 Bulk Transfer: Peripheral Mode

Bulk transactions are handled by endpoints other than endpoint 0. It is used to handle non-periodic, large bursty communication typically used for a transfer that use any available bandwidth and can also be delayed until bandwidth is available.

15.3.8.1.2.1 Bulk IN Transactions: Peripheral Mode

A Bulk IN transaction is used to transfer non-periodic data from the USB peripheral device to the host.

The following optional features are available for use with a Tx endpoint used in peripheral mode for Bulk IN transactions:

- Double packet buffering: When enabled, up to two packets can be stored in the FIFO awaiting transmission to the host. Double packet buffering is enabled by setting the DPB bit of TXFIFOSZ register (bit 4).
- DMA: If DMA is enabled for the endpoint, a DMA request will be generated whenever the endpoint is able to accept another packet in its FIFO. This feature allows the DMA controller to load packets into the FIFO without processor intervention

15.3.8.1.2.1.1 Bulk IN Transaction Setup: Peripheral Mode

In configuring a TX endpoint for bulk transactions, the TXMAXP register must be written with the maximum packet size (in bytes) for the endpoint. This value should be the same as the wMaxPacketSize field of the Standard Endpoint Descriptor for the endpoint and the PERI_TXCSR register (DMAEN and DMAMODE bit fields should be set when using DMA. Table 15-4 displays the PERI_TXCSR setting when used for Bulk transfer.

Table 15-4. PERI_TXCSR Register Bit Configuration for Bulk IN Transactions

Bit Field	Bit Name	Description
Bit 15	AUTOSET	Cleared to 0 if using DMA. For CPU Mode use, if AUTOSET bit is set, the TXPKTRDY bit will be automatically set when data of the maximum packet size is loaded into the FIFO.
Bit 14	ISO	Cleared to 0 for bulk mode operation.
Bit 13	MODE	Set to 1 to make sure the FIFO is enabled (only necessary if the FIFO is shared with an RX endpoint)
Bit 12	DMAEN	Set to 1 to enable DMA usage; not needed if CPU is being used to service the Tx Endpoint
Bit 11	FRCDATATOG	Cleared to 0 to allow normal data toggle operations.
Bit 10	DMAMODE	Set to 1 when DMA is used to service Tx FIFO.

When the endpoint is first configured (following a SET_CONFIGURATION or SET_INTERFACE command on Endpoint 0), the lower byte of PERI_TXCSR should be written to set the CLRDATATOG bit (bit 6). This will ensure that the data toggle (which is handled automatically by the controller) starts in the correct state.

Also if there are any data packets in the FIFO, indicated by the FIFONOTEMPTY bit (bit 1 of PERI_TXCSR) being set, they should be flushed by setting the FLUSHFIFO bit (bit 3 of PERI_TXCSR).

NOTE: It may be necessary to set this bit twice in succession if double buffering is enabled.

Copyright © 2011, Texas Instruments Incorporated

15.3.8.1.2.1.2 Bulk IN Operation: Peripheral Mode

When data is to be transferred over a Bulk IN pipe, a data packet needs to be loaded into the FIFO and the PERI_TXCSR register written to set the TXPKTRDY bit (bit 0). When the packet has been sent, the TXPKTRDY bit will be cleared by the USB controller and an interrupt generated to signify to the user/application that the next packet can be loaded into the FIFO. If double packet buffering is enabled, then after the first packet has been loaded and the TXPKTRDY bit set, the TXPKTRDY bit will immediately be cleared (will not wait for the loaded first packet to be driven out) by the USB controller and an interrupt generated so that a second packet can be loaded into the FIFO. The software should operate in the same way, loading a packet when it receives an interrupt, regardless of whether double packet buffering is enabled or not.

In the general case, the packet size must not exceed the size specified by the lower 11 bits of the TXMAXP register. This part of the register defines the payload (packet size) for transfers over the USB and is required by the USB Specification to be either 8, 16, 32, 64 (Full-Speed or High-Speed) or 512 bytes (High-Speed only).

The host may determine that all the data for a transfer has been sent by knowing the total amount of data that is expected. Alternatively it may infer that all the data has been sent when it receives a packet which is smaller than the maximum packet size configuration for that particular endpoint (TXMAXP[10-0]). In the latter case, if the total size of the data block is a multiple of this payload, it will be necessary for the function to send a null packet after all the data has been sent. This is done by setting TXPKTRDY when the next interrupt is received, without loading any data into the FIFO.

If large blocks of data are being transferred, then the overhead of calling an interrupt service routine to load each packet can be avoided by using the CPPI DMA. A separate section detailing the use of the DMA is discussed within a latter section. Suffix is to say that the PERI_TXCSR (DMAEN and DMAMODE) bit fields need to be set and the PERI_TXCSR[AUTOSET] bit cleared at the core level when using the DMA with an endpoint configured for any IN transaction/transfer.

15.3.8.1.2.1.3 Error Handling of Bulk IN Transfer: Peripheral Mode

If the software wants to shut down the Bulk IN pipe, it should set the SENDSTALL bit (bit 4 of PERI_TXCSR). When the controller receives the next IN token, it will send a STALL to the host, set the SENTSTALL bit (bit 5 of PERI_TXCSR) and generate an interrupt.

When the software receives an interrupt with the SENTSTALL bit (bit 5 of PERI_TXCSR) set, it should clear the SENTSTALL bit. It should however leave the SENDSTALL bit set until it is ready to re-enable the Bulk IN pipe.

NOTE: If the host failed to receive the STALL packet for some reason, it will send another IN token, so it is advisable to leave the SENDSTALL bit set until the software is ready to re-enable the Bulk IN pipe. When a pipe is re-enabled, the data toggle sequence should be restarted by setting the CLRDATATOG bit in the PERI_TXCSR register (bit 6).

15.3.8.1.2.2 Bulk OUT Transfer: Peripheral Mode

A Bulk OUT transaction is used to transfer non-periodic data from the host to the function controller.

The following optional features are available for use with an Rx endpoint used in peripheral mode for Bulk OUT transactions:

- Double packet buffering: When enabled, up to two packets can be stored in the FIFO on reception from the host. Double packet buffering is enabled by setting the DPB bit of the RXFIFOSZ register (bit 4).
- DMA: If DMA is enabled for the endpoint, a DMA request will be generated whenever the endpoint has a packet in its FIFO. This feature can be used to allow the DMA controller to unload packets from the FIFO without processor intervention.

NOTE: When DMA is enabled, endpoint interrupt will not be generated for completion of packet reception. Endpoint interrupt will be generated only in the error conditions.

Copyright © 2011, Texas Instruments Incorporated

15.3.8.1.2.2.1 Bulk OUT Transfer Setup: Peripheral Mode

In configuring an Rx endpoint for Bulk OUT transactions, the RXMAXP register must be written with the maximum packet size (in bytes) for the endpoint. This value should be the same as the wMaxPacketSize field of the Standard Endpoint Descriptor for the endpoint. When using DMA for Rx Endpoints, the PERI_RXCSR needs to have its DMAEN bit set and have its AUTOCLEAR and DMAMODE bits cleared. In addition, the relevant interrupt enable bit in the INTRRXE register should be set (if an interrupt is required for this endpoint) and the PERI_RXCSR register should be set as shown in Table 15-5.

Table 15-5. PERI_RXCSR Register Bit Configuration for Bulk OUT Transactions

Bit Field	Bit Name	Description
Bit 15	AUTOCLEAR	Cleared to 0 if using DMA. In CPU Mode of usage, if the CPU sets AUTOCLEAR bit, the RXPKTRDY bit will be automatically cleared when a packet of RXMAXP bytes has been unloaded from the Receive FIFO.
Bit 14	ISO	Cleared to 0 to enable Bulk protocol.
Bit 13	DMAEN	Set to 1 if a DMA request is required for this Rx endpoint.
Bit 12	DISNYET	Cleared to 0 to allow normal PING flow control. This will affect only high speed transactions.
Bit 11	DMAMODE	Always clear this bit to 0.

When the Rx endpoint is first configured (following a SET_CONFIGURATION or SET_INTERFACE command on Endpoint 0), the lower byte of PERI_RXCSR should be written to set the CLRDATATOG bit (bit 7). This will ensure that the data toggle (which is handled automatically by the USB controller) starts in the correct state.

Also if there are any data packets in the FIFO (indicated by the RXPKTRDY bit (bit 0 of PERI_RXCSR) being set), they should be flushed by setting the FLUSHFIFO bit (bit 4 of PERI_RXCSR).

NOTE: It may be necessary to set this bit twice in succession if double buffering is enabled.

15.3.8.1.2.2.2 Bulk OUT Operation: Peripheral Mode

When a data packet is received by a Bulk Rx endpoint, the RXPKTRDY bit (bit 0 of PERI_RXCSR) is set and an interrupt is generated. The software should read the RXCOUNT register for the endpoint to determine the size of the data packet. The data packet should be read from the FIFO, and then the RXPKTRDY bit should be cleared.

The packets received should not exceed the size specified in the RXMAXP register (as this should be the value set in the wMaxPacketSize field of the endpoint descriptor sent to the host). When a block of data larger than wMaxPacketSize needs to be sent to the function, it will be sent as multiple packets. All the packets will be wMaxPacketSize in size, except the last packet which will contain the residue. The software may use an application specific method of determining the total size of the block and hence when the last packet has been received. Alternatively it may infer that the entire block has been received when it receives a packet which is less than wMaxPacketSize in size. (If the total size of the data block is a multiple of wMaxPacketSize, a null data packet will be sent after the data to signify that the transfer is complete.)

In the general case, the application software will need to read each packet from the FIFO individually. If large blocks of data are being transferred, the overhead of calling an interrupt service routine to unload each packet can be avoided by using DMA.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

15.3.8.1.2.2.3 Bulk OUT Error Handling: Peripheral Mode

If the software wants to shut down the Bulk OUT pipe, it should set the SENDSTALL bit (bit 5 of PERI_RXCSR). When the controller receives the next packet it will send a STALL to the host, set the SENTSTALL bit (bit 6 of PERI_RXCSR) and generate an interrupt.

When the software receives an interrupt with the SENTSTALL bit (bit 6 of PERI_RXCSR) set, it should clear this bit. It should however leave the SENDSTALL bit set until it is ready to re-enable the Bulk OUT pipe.

NOTE: If the host failed to receive the STALL packet for some reason, it will send another packet, so it is advisable to leave the SENDSTALL bit set until the software is ready to re-enable the Bulk OUT pipe. When a Bulk OUT pipe is re-enabled, the data toggle sequence should be restarted by setting the CLRDATATOG bit (bit 7) in the PERI_RXCSR register.

15.3.8.1.3 Interrupt Transfer: Peripheral Mode

An Interrupt IN transaction uses the same protocol as a Bulk IN transaction and the configuration and operation mentioned on prior sections apply to Interrupt transfer too with minor changes. Similarly, an Interrupt OUT transaction uses almost the same protocol as a Bulk OUT transaction and can be used the same way.

Tx endpoints in the USB controller have one feature for Interrupt IN transactions that they do not support in Bulk IN transactions. In Interrupt IN transactions, the endpoints support continuous toggle of the data toggle bit.

This feature is enabled by setting the FRCDATATOG bit in the PERI_TXCSR register (bit 11). When this bit is set, the controller will consider the packet as having been successfully sent and toggle the data bit for the endpoint, regardless of whether an ACK was received from the host.

Another difference is that interrupt endpoints do not support PING flow control. This means that the controller should never respond with a NYET handshake, only ACK/NAK/STALL. To ensure this, the DISNYET bit in the PERI_RXCSR register (bit 12) should be set to disable the transmission of NYET handshakes in high-speed mode.

Though DMA can be used with an interrupt OUT endpoint, it generally offers little benefit as interrupt endpoints are usually expected to transfer all their data in a single packet.

15.3.8.1.4 Isochronous Transfer: Peripheral Mode

Isochronous transfers are used when working with isochronous data. Isochronous transfers provide periodic, continuous communication between host and device.

15.3.8.1.4.1 Isochronous IN Transactions: Peripheral Mode

An Isochronous IN transaction is used to transfer periodic data from the function controller to the host.

The following optional features are available for use with a Tx endpoint used in Peripheral mode for Isochronous IN transactions:

- Double packet buffering: When enabled, up to two packets can be stored in the FIFO awaiting transmission to the host. Double packet buffering is enabled by setting the DPB bit of TXFIFOSZ register (bit 4).

  NOTE: Double packet buffering is generally advisable for isochronous transactions in order to avoid underrun errors as described in later section.
- DMA: If DMA is enabled for the endpoint, a DMA request will be generated whenever the endpoint is able to accept another packet in its FIFO. This feature allows the DMA controller to load packets into the FIFO without processor intervention.
  However, this feature is not particularly useful with Isochronous endpoints because the packets transferred are often not maximum packet size and the PERI_TXCSR register needs to be accessed following every packet to check for Underrun errors.
  When DMA is enabled and DMAMODE bit of PERI_TXCSR is set, endpoint interrupt will not be generated for completion of packet transfer. Endpoint interrupt will be generated only in the error conditions.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

15.3.8.1.4.1.1 Isochronous IN Transfer Setup: Peripheral Mode

In configuring a Tx endpoint for Isochronous IN transactions, the TXMAXP register must be written with the maximum packet size (in bytes) for the endpoint. This value should be the same as the wMaxPacketSize field of the Standard Endpoint Descriptor for the endpoint. In addition, the relevant interrupt enable bit in the INTRTXE register should be set (if an interrupt is required for this endpoint) and the PERI_TXCSR register should be set as shown in Table 15-6.

Table 15-6. PERI_TXCSR Register Bit Configuration for Isochronous IN Transactions

Bit Field	Bit Name	Description
Bit 14	ISO	Set to 1 to enable Isochronous transfer protocol.
Bit 13	MODE	Set to 1 to ensure the FIFO is enabled (only necessary if the FIFO is shared with an Rx endpoint).
Bit 12	DMAEN	Set to 1 if DMA Requests have to be enabled.
Bit 11	FRCDATATOG	Ignored in Isochronous mode.
Bit 10	DMAMODE	Set to 1 when DMA is enabled.

15.3.8.1.4.1.2 Isochronous IN Transfer Operation: Peripheral Mode

An isochronous endpoint does not support data retries, so if data underrun is to be avoided, the data to be sent to the host must be loaded into the FIFO before the IN token is received. The host will send one IN token per frame (or microframe in High-speed mode), however the timing within the frame (or microframe) can vary. If an IN token is received near the end of one frame and then at the start of the next frame, there will be little time to reload the FIFO. For this reason, double buffering of the endpoint is usually necessary.

An interrupt is generated whenever a packet is sent to the host and the software may use this interrupt to load the next packet into the FIFO and set the TXPKTRDY bit in the PERI_TXCSR register (bit 0) in the same way as for a Bulk Tx endpoint. As the interrupt could occur almost any time within a frame(/microframe), depending on when the host has scheduled the transaction, this may result in irregular timing of FIFO load requests. If the data source for the endpoint is coming from some external hardware, it may be more convenient to wait until the end of each frame(/microframe) before loading the FIFO as this will minimize the requirement for additional buffering. This can be done by using either the SOF interrupt or the external SOF_PULSE signal from the controller to trigger the loading of the next data packet. The SOF_PULSE is generated once per frame(/microframe) when a SOF packet is received. (The controller also maintains an external frame(/microframe) counter so it can still generate a SOF_PULSE when the SOF packet has been lost.) The interrupts may still be used to set the TXPKTRDY bit in PERI_TXCSR (bit 0) and to check for data overruns/underruns.

Starting up a double-buffered Isochronous IN pipe can be a source of problems. Double buffering requires that a data packet is not transmitted until the frame(/microframe) after it is loaded. There is no problem if the function loads the first data packet at least a frame(/microframe) before the host sets up the pipe (and therefore starts sending IN tokens). But if the host has already started sending IN tokens by the time the first packet is loaded, the packet may be transmitted in the same frame(/microframe) as it is loaded, depending on whether it is loaded before, or after, the IN token is received. This potential problem can be avoided by setting the ISOUPDATE bit in the POWER register (bit 7). When this bit is set, any data packet loaded into an Isochronous Tx endpoint FIFO will not be transmitted until after the next SOF packet has been received, thereby ensuring that the data packet is not sent too early.

15.3.8.1.4.1.3 Isochronous IN Error Handling: Peripheral Mode

If the endpoint has no data in its FIFO when an IN token is received, it will send a null data packet to the host and set the UNDERRUN bit in the PERI_TXCSR register (bit 2). This is an indication that the software is not supplying data fast enough for the host. It is up to the application to determine how this error condition is handled.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

If the software is loading one packet per frame(/microframe) and it finds that the TXPKTRDY bit in the PERI_TXCSR register (bit 0) is set when it wants to load the next packet, this indicates that a data packet has not been sent (perhaps because an IN token from the host was corrupted). It is up to the application how it handles this condition: it may choose to flush the unsent packet by setting the FLUSHFIFO bit in the PERI_TXCSR register (bit 3), or it may choose to skip the current packet.

15.3.8.1.4.2 Isochronous OUT Transactions: Peripheral Mode

An isochronous OUT transaction is used to transfer periodic data from the host to the function controller.

Following optional features are available for use with an Rx endpoint used in Peripheral mode for Isochronous OUT transactions:

- Double packet buffering: When enabled, up to two packets can be stored in the FIFO on reception from the host. Double packet buffering is enabled by setting the DPB bit of RXFIFOSZ register (bit 4). **NOTE:** Double packet buffering is generally advisable for Isochronous transactions in order to avoid overrun errors.
- DMA: If DMA is enabled for the endpoint, a DMA request will be generated whenever the endpoint has a packet in its FIFO. This feature can be used to allow the DMA controller to unload packets from the FIFO without processor intervention.
  However, this feature is not particularly useful with Isochronous endpoints because the packets transferred are often not maximum packet size and the PERI_RXCSR register needs to be accessed following every packet to check for Overrun or CRC errors.
  When DMA is enabled, endpoint interrupt will not be generated for completion of packet reception. Endpoint interrupt will be generated only in the error conditions.

15.3.8.1.4.2.1 Isochronous OUT Setup: Peripheral Mode

In configuring an Rx endpoint for Isochronous OUT transactions, the RXMAXP register must be written with the maximum packet size (in bytes) for the endpoint. This value should be the same as the wMaxPacketSize field of the Standard Endpoint Descriptor for the endpoint. In addition, the relevant interrupt enable bit in the INTRRXE register should be set (if an interrupt is required for this endpoint) and the PERI_RXCSR register should be set as shown in Table 15-7.

Table 15-7. PERI_RXCSR Register Bit Configuration for Isochronous OUT Transactions

Bit Field	Bit Name	Description
Bit 15	AUTOCLEAR	Cleared to 0 if using DMA. In CPU Mode of usage, if the CPU sets AUTOCLEAR bit, the RXPKTRDY bit will be automatically cleared when a packet of RXMAXP bytes has been unloaded from the Receive FIFO.
Bit 14	ISO	Set to 1 to configure endpoint usage for Isochronous transfer.
Bit 13	DMAEN	Set to 1 if a DMA request is required for this Rx endpoint.
Bit 12	DISNYET	Ignored in Isochronous Mode.
Bit 11	DMAMODE	Always clear this bit to 0.

DRAFT ONLY

15.3.8.1.4.2.2 Isochronous OUT Operation: Peripheral Mode

An Isochronous endpoint does not support data retries so, if a data overrun is to be avoided, there must be space in the FIFO to accept a packet when it is received. The host will send one packet per frame (or microframe in High-speed mode); however, the time within the frame can vary. If a packet is received near the end of one frame(/microframe) and another arrives at the start of the next frame, there will be little time to unload the FIFO. For this reason, double buffering of the endpoint is usually necessary.

An interrupt is generated whenever a packet is received from the host and the software may use this interrupt to unload the packet from the FIFO and clear the RXPKTRDY bit in the PERI_RXCSR register (bit 0) in the same way as for a Bulk Rx endpoint. As the interrupt could occur almost any time within a frame(/microframe), depending on when the host has scheduled the transaction, the timing of FIFO unload requests will probably be irregular. If the data sink for the endpoint is going to some external hardware, it may be better to minimize the requirement for additional buffering by waiting until the end of each frame(/microframe) before unloading the FIFO. This can be done by using either the SOF interrupt or the external SOF_PULSE signal from the controller to trigger the unloading of the data packet. The SOF_PULSE is generated once per frame(/microframe) when a SOF packet is received. (The controller also maintains an external frame(/microframe) counter so it can still generate a SOF_PULSE when the SOF packet has been lost.) The interrupts may still be used to clear the RXPKTRDY bit in PERI_RXCSR and to check for data overruns/underruns.

15.3.8.1.4.2.3 Isochronous OUT Error Handling: Peripheral Mode

If there is no space in the FIFO to store a packet when it is received from the host, the OVERRUN bit in the PERI_RXCSR register (bit 2) will be set. This is an indication that the software is not unloading data fast enough for the host. It is up to the application to determine how this error condition is handled

If the controller finds that a received packet has a CRC error, it will still store the packet in the FIFO and set the RXPKTRDY bit (bit 0 of PERI_RXCSR) and the DATAERROR bit (bit 3 of PERI_RXCSR). It is left up to the application to determine how this error condition is handled.

The number of USB packets sent in any microframe will depend on the amount of data to be transferred, and is indicated through the PIDs used for the individual packets. If the indicated number of packets have not been received by the end of a microframe, the INCOMPRX bit (bit 8) bit in the PERI_RXCSR register will be set to indicate that the data in the FIFO is incomplete. Equally, if a packet of the wrong data type is received, then the PID Error bit is the PERI_RXCSR register will be set. In each case, an interrupt will, however, still be generated to allow the data that has been received to be read from the FIFO.

Note: The circumstances in which a PID Error or INCOMPRX is reported depends on the precise sequence of packets received.

When the core is operating in peripheral mode, the details are in Table 15-8.

Table 15-8. Isochronous OUT Error Handling: Peripheral Mode

No. Packet(s) Expected	Data Packet(s) Received	Response
1	DATA0	OK

15.3.8.2 USB Controller Host Mode Operation

The USB controller assumes the role of a host when the USBx_ID pin state is grounded or USB Mode Register[iddig=bit8] is cleared to 0 (provided that iddig_mux, which is bit7 of USBnMODE is also set to 1) by the user application prior to the controller goes into session. When the USB controller go into session, application/firmware sets the DEVCTL[SESSION] bit to 1, it will assume the role of a host.

- Entry into Suspend mode. When operating as a host, the USB controller can be prompted to go into Suspend mode by setting the SUSPENDM bit in the POWER register. When this bit is set, the controller will complete the current transaction then stop the transaction scheduler and frame counter. No further transactions will be started and no SOF packets will be generated.
  If the ENSUSPM bit (bit 0 of POWER register) is set, the UTMI+ PHY will go into low-power mode when the controller goes into suspend mode.
- Sending Resume Signaling. When the application requires the controller to leave suspend mode, it needs to clear the SUSPENDM bit in the POWER register, set the RESUME bit and leave it set for 20ms. While the RESUME bit is high, the controller will generate Resume signaling on the bus. After 20 ms, the CPU should clear the RESUME bit, at which point the frame counter and transaction scheduler will be started.
- Responding to Remote Wake-up. If Resume signaling is detected from the target while the controller is in suspend mode, the UTMI+ PHY will be brought out of low-power mode and UTMI clock is restarted. The controller will then exit suspend mode and automatically set the RESUME bit in the POWER register (bit 2) to ‘1’ to take over generating the Resume signaling from the target. If the resume interrupt is enabled, an interrupt will be generated.
- Reset Signaling. If the RESET bit in the POWER register (bit 3) is set while the controller is in Host mode, it will generate Reset signaling on the bus. If the HSENAB bit in the POWER register (bit 5) was set, it will also try to negotiate for high-speed operation. The software should keep the RESET bit set for at least 20 ms to ensure correct resetting of the target device. After the software has cleared the bit, the controller will start its frame counter and transaction scheduler. Whether high-speed operation is selected will be indicated by HSMODE bit of POWER register (bit 4).

15.3.8.2.1 Control Transactions: Host Mode

Host control transactions are conducted through Endpoint 0 and the software is required to handle all the Standard Device Requests that may be sent or received via Endpoint 0 (as described in Universal Serial Bus Specification, Revision 2.0). Endpoint 0 can only be serviced via CPU and DMA mode can not be used.

There are three categories of Standard Device Requests to be handled: Zero Data Requests (in which all the information is included in the command); Write Requests (in which the command will be followed by additional data); and Read Requests (in which the device is required to send data back to the host).

1. Zero Data Requests comprise a SETUP command followed by an IN Status Phase.
2. Write Requests comprise a SETUP command, followed by an OUT Data Phase which is in turn followed by an IN Status Phase.
3. Read Requests comprise a SETUP command, followed by an IN Data Phase which is in turn followed by an OUT Status Phase.

A timeout may be set to limit the length of time for which the host controller will retry a transaction which is continually NAKed by the target. This limit can be between 2 and 2 15 frames/microframes and is set through the NAKLIMIT0 register.

The following sections describe the actions that the CPU needs to take in issuing these different types of request through looking at the steps to take in the different phases of a control transaction.

Note: Before initiating any transactions as a Host, the FADDR register needs to be set to address the peripheral device. When the device is first connected, FADDR should be set to zero. After a SET_ADDRESS command is issued, FADDR should be set the target's new address.

15.3.8.2.1.1 Setup Phase of Control Transaction: Host Mode

For the SETUP Phase of a control transaction (Figure 15-8), the software driving the USB host device needs to:

1. Load the 8 bytes of the required Device request command into the Endpoint 0 FIFO
2. Set SETUPPKT and TXPKTRDY (bits 3 and 1 of HOST_CSR0, respectively).
   NOTE: These bits must be set together.
   The controller then proceeds to send a SETUP token followed by the 8-byte command/request to Endpoint 0 of the addressed device, retrying as necessary. *Note:* On errors, the controller retries the transaction three times.
3. At the end of the attempt to send the 8-byte request data, the controller will generate an Endpoint 0 interrupt. The software should then read HOST_CSR0 to establish whether the RXSTALL bit (bit 2), the ERROR bit (bit 4) or the NAK_TIMEOUT bit (bit 7) has been set.
   If RXSTALL is set, it indicates that the target did not accept the command (for example, because it is not supported by the target device) and so has issued a STALL response. If ERROR is set, it means that the controller has tried to send the SETUP Packet and the following data packet three times without getting any response.
   If NAK_TIMEOUT is set, it means that the controller has received a NAK response to each attempt to send the SETUP packet, for longer than the time set in HOST_NAKLIMIT0. The controller can then be directed either to continue trying this transaction (until it times out again) by clearing the NAK_TIMEOUT bit or to abort the transaction by flushing the FIFO before clearing the NAK_TIMEOUT bit.
4. If none of RXSTALL, ERROR or NAK_TIMEOUT is set, the SETUP Phase has been correctly ACKed and the software should proceed to the following IN Data Phase, OUT Data Phase or IN Status Phase specified for the particular Standard Device Request.

DRAFT ONLY

15.3.8.2.1.2 Data Phase (IN Data Phase) of a Control Transaction: Host Mode

For the IN Data Phase of a control transaction (Figure 15-9), the software driving the USB host device needs to

1. Set REQPKT bit of HOST_CSR0 (bit 5)
2. Wait while the controller sends the IN token and receives the required data back.
3. When the controller generates the Endpoint 0 interrupt, read HOST_CSR0 to establish whether the RXSTALL bit (bit 2), the ERROR bit (bit 4), the NAK_TIMEOUT bit (bit 7) or RXPKTRDY bit (bit 0) has been set.
   If RXSTALL is set, it indicates that the target has issued a STALL response.

Copyright © 2011, Texas Instruments Incorporated

If ERROR is set, it means that the controller has tried to send the required IN token three times without getting any response. If NAK_TIMEOUT bit is set, it means that the controller has received a NAK response to each attempt to send the IN token, for longer than the time set in HOST_NAKLIMIT0. The controller can then be directed either to continue trying this transaction (until it times out again) by clearing the NAK_TIMEOUT bit or to abort the transaction by clearing REQPKT before clearing the NAK_TIMEOUT bit

4. If RXPKTRDY has been set, the software should read the data from the Endpoint 0 FIFO, then clear RXPKTRDY.
5. If further data is expected, the software should repeat Steps 1-4.

When all the data has been successfully received, the CPU should proceed to the OUT Status Phase of the Control Transaction.

Figure 15-9. Flow Chart of Data Stage (IN Data Phase) of a Control Transfer in Host Mode

15.3.8.2.1.3 Data Phase (OUT Data Phase) of a Control Transaction: Host Mode

For the OUT Data Phase of a control transaction (Figure 15-10), the software driving the USB host device needs to:

Copyright © 2011, Texas Instruments Incorporated

1. Load the data to be sent into the endpoint 0 FIFO.
2. Set the TXPKTRDY bit of HOST_CSR0 (bit 1). The controller then proceeds to send an OUT token followed by the data from the FIFO to Endpoint 0 of the addressed device, retrying as necessary.
3. At the end of the attempt to send the data, the controller will generate an Endpoint 0 interrupt. The software should then read HOST_CSR0 to establish whether the RXSTALL bit (bit 2), the ERROR bit (bit 4) or the NAK_TIMEOUT bit (bit 7) has been set.
   If RXSTALL bit is set, it indicates that the target has issued a STALL response.
   If ERROR bit is set, it means that the controller has tried to send the OUT token and the following data packet three times without getting any response. If NAK_TIMEOUT is set, it means that the controller has received a NAK response to each attempt to send the OUT token, for longer than the time set in the HOST_NAKLIMIT0 register. The controller can then be directed either to continue trying this transaction (until it times out again) by clearing the NAK_TIMEOUT bit or to abort the transaction by flushing the FIFO before clearing the NAK_TIMEOUT bit.
   If none of RXSTALL, ERROR or NAKLIMIT is set, the OUT data has been correctly ACKed.
4. If further data needs to be sent, the software should repeat Steps 1-3.
   When all the data has been successfully sent, the software should proceed to the IN Status Phase of the Control Transaction.

15.3.8.2.1.4 Status Phase (Status for OUT Data Phase or Setup Phase) of a Control Transaction: Host Mode

IN Status Phase of a control transfer exists for a Zero Data Request or for a Write Request of a control transfer. The IN Status Phase follows the Setup Stage, if no Data Stage of a control transfer exists, or OUT Data Phase of a Data Stage of a control transfer.

For the IN Status Phase of a control transaction (Figure 15-11), the software driving the USB Host device needs to:

1. Set the STATUSPKT and REQPKT bits of HOST_CSR0 (bit 6 and bit 5, respectively).
2. Wait while the controller sends an IN token and receives a response from the USB peripheral device.
3. When the controller generates the Endpoint 0 interrupt, read HOST_CSR0 to establish whether the RXSTALL bit (bit 2), the ERROR bit (bit 4), the NAK_TIMEOUT bit (bit 7) or RXPKTRDY bit (bit 0) has been set.

Copyright © 2011, Texas Instruments Incorporated

If RXSTALL bit is set, it indicates that the target could not complete the command and so has issued a STALL response.
If ERROR bit is set, it means that the controller has tried to send the required IN token three times without getting any response.
If NAK_TIMEOUT bit is set, it means that the controller has received a NAK response to each attempt to send the IN token, for longer than the time set in the HOST_NAKLIMIT0 register. The controller can then be directed either to continue trying this transaction (until it times out again) by clearing the NAK_TIMEOUT bit or to abort the transaction by clearing REQPKT bit and STATUSPKT bit before clearing the NAK_TIMEOUT bit.

4. The CPU should clear the STATUSPPKT bit of HOST_CSR0 together with (i.e., in the same write operation as) RxPktRdy if this has been set.

Figure 15-11. Flow Chart of Status Stage of Zero Data Request or Write Request of a Control Transfer in Host Mode

15.3.8.2.1.5 Status Phase for a Read Request of a Control Transaction: Host Mode

OUT Status Phase of a control transfer exist for a Read Request or a control transfer where data was received by the host controller. The OUT Status phase follows the IN Data Stage of a control transfer.

Copyright © 2011, Texas Instruments Incorporated

For the OUT Status Phase of a control transaction (Figure 15-12), the CPU driving the host device needs to:

1. Set STATUSPKT and TXPKTRDY bits of HOST_CSR0 (bit 6 and bit 1, respectively).
   NOTE: These bits need to be set together
2. Wait while the controller sends the OUT token and a zero-length DATA1 packet.
3. At the end of the attempt to send the data, the controller will generate an Endpoint 0 interrupt. The software should then read HOST_CSR0 to establish whether the RXSTALL bit (bit 2), the ERROR bit (bit 4) or the NAK_TIMEOUT bit (bit 7) has been set.
   If RXSTALL bit is set, it indicates that the target could not complete the command and so has issued a STALL response.
   If ERROR bit is set, it means that the controller has tried to send the STATUS Packet and the following data packet three times without getting any response.
   If NAK_TIMEOUT bit is set, it means that the controller has received a NAK response to each attempt to send the IN token, for longer than the time set in the HOST_NAKLIMIT0 register. The controller can then be directed either to continue trying this transaction (until it times out again) by clearing the NAK_TIMEOUT bit or to abort the transaction by flushing the FIFO before clearing the NAK_TIMEOUT bit.
4. If none of RXSTALL, ERROR or NAK_TIMEOUT bits is set, the STATUS Phase has been correctly ACKed.

15.3.8.2.2 Bulk Transfer: Host Mode

Bulk transactions are handled by endpoints other than endpoint 0. It is used to handle non-periodic, large bursty communication typically used for a transfer that use any available bandwidth and can also be delayed until bandwidth is available.

15.3.8.2.2.1 Bulk IN Transactions: Host Mode

A Bulk IN transaction may be used to transfer non-periodic data from the external USB peripheral to the host.

Copyright © 2011, Texas Instruments Incorporated

The following optional features are available for use with an Rx endpoint used in host mode to receive the data:

- Double packet buffering: When enabled, up to two packets can be stored in the FIFO on reception from the host. This allows that one packet can be received while another is being read. Double packet buffering is enabled by setting the DPB bit of RXFIFOSZ register (bit 4).
- DMA: If DMA is enabled for the endpoint, a DMA request will be generated whenever the endpoint has a packet in its FIFO. This feature can be used to allow the DMA controller to unload packets from the FIFO without processor intervention.
  When DMA is enabled, endpoint interrupt will not be generated for completion of packet reception. Endpoint interrupt will be generated only in the error conditions. For more information see section on CPPI DMA

15.3.8.2.2.1.1 Bulk IN Setup: Host Mode

Before initiating any Bulk IN Transactions in Host mode:

- The HOST_RXTYPE register for the endpoint that is to be used needs to be programmed as:
  - Operating speed in the SPEED bit field (bits 7 and 6).
  - Set 10 (binary value) in the PROT field for bulk transfer.
  - Endpoint Number of the target device in RENDPN field. This is the endpoint number contained in the Rx endpoint descriptor returned by the target device during enumeration.
- The RXMAXP register for the controller endpoint must be written with the maximum packet size (in bytes) for the transfer. This value should be the same as the wMaxPacketSize field of the Standard Endpoint Descriptor for the target endpoint.
- The HOST_RXINTERVAL register needs to be written with the required value for the NAK limit (2-215 frames/microframes), or set to zero if the NAK timeout feature is not required.
- The relevant interrupt enable bit in the INTRRXE register should be set (if an interrupt is required for this endpoint).

  Note: Whether interrupt is handled from PDR level or Core level, interrupt is required to be enabled at the core level. See details on Core Interrupt registers, CTRLR register, and sections on Interrupt Handling
- The AUTOREQ bit field should be used only when servicing transfers using CPU mode and must be cleared when using DMA Mode. For DMA Mode, dedicated registers USB0/1 Req Registers exist and the HOST_RXCSR[AUTOREQ] should be cleared.
  When DMA is enabled, the following bits of HOST_RXCSR register should be set as:
  - Clear AUTOCLEAR.
  - Set DMAEN (bit 13) to 1 if a DMA request is required for this endpoint.
  - Clear DSINYET (bit 12) to 0 to allow normal PING flow control. This will affect only High Speed transactions.
  - Clear DMAMODE (bit 11) to 0.

    Note: If DMA is enabled, the USB0/1 Auto Req register can be set for generating IN tokens automatically after receiving the data. Set the bit field RXn_AUTOREQ (where n is the endpoint number) with binary value 01 or 11.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

When the endpoint is first configured, the endpoint data toggle should be cleared to 0 either by using the DATATOGWREN and DATATOG bits of HOST_RXCSR (bit 10 and bit 9) to toggle the current setting or by setting the CLRDATATOG bit of HOST_RXCSR (bit 7). This will ensure that the data toggle (which is handled automatically by the controller) starts in the correct state. Also if there are any data packets in the FIFO (indicated by the RXPKTRDY bit (bit 0 of HOST_RXCSR) being set), they should be flushed by setting the FLUSHFIFO bit of HOST_RXCSR (bit 4).

NOTE: It may be necessary to set this bit twice in succession if double buffering is enabled.

15.3.8.2.2.1.2 Bulk IN Operation: Host Mode

When Bulk data is required from the USB peripheral device, the software should set the REQPKT bit in the corresponding HOST_RXCSR register (bit 5). The controller will then send an IN token to the selected peripheral endpoint and waits for data to be returned.

If data is correctly received, RXPKTRDY bit of HOST_RXCSR (bit 0) is set. If the USB peripheral device responds with a STALL, RXSTALL bit (bit 6 of HOST_RXCSR) is set. If a NAK is received, the controller tries again and continues to try until either the transaction is successful or the POLINTVL_NAKLIMIT set in the HOST_RXINTERVAL register is reached. If no response at all is received, two further attempts are made before the controller reports an error by setting the ERROR bit of HOST_RXCSR (bit 2).

The controller then generates the appropriate endpoint interrupt, whereupon the software should read the corresponding HOST_RXCSR register to determine whether the RXPKTRDY, RXSTALL, ERROR or DATAERR_NAKTIMEOUT bit is set and act accordingly. If the DATAERR_NAKTIMEOUT bit is set, the controller can be directed either to continue trying this transaction (until it times out again) by clearing the DATAERR_NAKTIMEOUT bit or to abort the transaction by clearing REQPKT bit before clearing the DATAERR_NAKTIMEOUT bit.

The packets received should not exceed the size specified in the RXMAXP register (as this should be the value set in the wMaxPacketSize field of the endpoint descriptor sent to the host).

In the general case, the application software (if CPU is servicing the endpoint) will need to read each packet from the FIFO individually. If large blocks of data are being transferred, the overhead of calling an interrupt service routine to unload each packet can be avoided by using DMA.

Note: When using DMA, see CPPI DMA section for the proper configuration of the core register, HOST_RXCSR.

15.3.8.2.2.1.3 Bulk IN Error Handling: Host Mode

If the target wants to shut down the Bulk IN pipe, it will send a STALL response to the IN token. This will result in the RXSTALL bit of HOST_RXCSR (bit 6) being set.

15.3.8.2.2.2 Bulk OUT Transactions: Host Mode

A Bulk OUT transaction may be used to transfer non-periodic data from the host to the USB peripheral.

Following optional features are available for use with a Tx endpoint used in Host mode to transmit this data:

- Double packet buffering: When enabled, up to two packets can be stored in the FIFO awaiting transmission to the peripheral device. Double packet buffering is enabled by setting the DPB bit of TXFIFOSZ register (bit 4).
- DMA: If DMA is enabled for the endpoint, a DMA request will be generated whenever the endpoint is able to accept another packet in its FIFO. This feature can be used to allow the DMA controller to load packets into the FIFO without processor intervention. For more information on using DMA, consult the section discussing CPPI DMA.
  When DMA is enabled and DMAMODE bit in HOST_TXCSR register is set, an endpoint interrupt will not be generated for completion of packet reception. An endpoint interrupt will be generated only in the error conditions.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

15.3.8.2.2.2.1 Bulk OUT Setup: Host Mode

Before initiating any bulk OUT transactions:

- The target function address needs to be set in the TXFUNCADDR register for the selected controller endpoint. (TXFUNCADDR register is available for all endpoints from EP0 to EP15.)
- The HOST_TXTYPE register for the endpoint that is to be used needs to be programmed as:
  - Operating speed in the SPEED bit field (bits 7 and 6).
  - Set PROT field to 10b for bulk transfer.
  - Enter Endpoint Number of the target device in TENDPN field. This is the endpoint number contained in the OUT(Tx) endpoint descriptor returned by the target device during enumeration.
- The TXMAXP register for the controller endpoint must be written with the maximum packet size (in bytes) for the transfer. This value should be the same as the wMaxPacketSize field of the Standard Endpoint Descriptor for the target endpoint.
- The HOST_TXINTERVAL register needs to be written with the required value for the NAK limit (2-215 frames/microframes), or set to zero if the NAK timeout feature is not required.
- The relevant interrupt enable bit in the INTRTXE register should be set (if an interrupt is required for this endpoint).
- The following bits of HOST_TXCSR register should be set as:
  - Set the MODE bit (bit 13) to 1 to ensure the FIFO is enabled (only necessary if the FIFO is shared with an Rx endpoint).
  - Clear the FRCDATATOG bit (bit 11) to 0 to allow normal data toggle operations.
  - Clear/Set AUTOSET bit (bit 15). The setting of this bit depends on the desire of the user/application in automatically setting the TXPKTRDY bit when servicing transactions using CPU.

Note: If DMA is needs to be used in place of the CPU, the following table displays the setting of the core register HOST_TXCSR register in Host mode. For the CPPI DMA registers settings consult the section on CPPI DMA within this document.

Bit Field	Bit Name	Description
Bit 15	AUTOSET	Cleared to 0 if using DMA. For CPU Mode use, if AUTOSET bit is set, the TXPKTRDY bit will be automatically set when data of the maximum packet size is loaded into the FIFO.
Bit 14	ISO	Cleared to 0 for bulk mode operation.
Bit 13	MODE	Set to 1 to make sure the FIFO is enabled (only necessary if the FIFO is shared with an RX endpoint)
Bit 12	DMAEN	Set to 1 to enable DMA usage; not needed if CPU is being used to service the Tx Endpoint
Bit 11	FRCDATATOG	Cleared to 0 to allow normal data toggle operations.
Bit 10	DMAMODE	Set to 1 when DMA is used to service Tx FIFO.

When the endpoint is first configured, the endpoint data toggle should be cleared to 0 either by using the DATATOGWREN bit and DATATOG bit of HOST_TXCSR (bit 9 and bit 8) to toggle the current setting or by setting the CLRDATATOG bit of HOST_TXCSR (bit 6). This will ensure that the data toggle (which is handled automatically by the controller) starts in the correct state. Also, if there are any data packets in the FIFO (indicated by the FIFONOTEMPTY bit of HOST_TXCSR register (bit 1) being set), they should be flushed by setting the FLUSHFIFO bit (bit 3 of HOST_TXCSR).

NOTE: It may be necessary to set this bit twice in succession if double buffering is enabled.

15.3.8.2.2.2.2 Bulk OUT Operation: Host Mode

When Bulk data is required to be sent to the USB peripheral device, the software should write the first packet of the data to the FIFO (or two packets if double-buffered) and set the TXPKTRDY bit in the corresponding HOST_TXCSR register (bit 0). The controller will then send an OUT token to the selected peripheral endpoint, followed by the first data packet from the FIFO.

If data is correctly received by the peripheral device, an ACK should be received whereupon the controller will clear TXPKTRDY bit of HOST_TXCSR (bit 0). If the USB peripheral device responds with a STALL, the RXSTALL bit (bit 5) of HOST_TXCSR is set. If a NAK is received, the controller tries again and continues to try until either the transaction is successful or the NAK limit set in the HOST_TXINTERVAL register is reached. If no response at all is received, two further attempts are made before the controller reports an error by setting ERROR bit in HOST_TXCSR (bit 2).

The controller then generates the appropriate endpoint interrupt, whereupon the software should read the corresponding HOST_TXCSR register to determine whether the RXSTALL (bit 5), ERROR (bit 2) or NAK_TIMEOUT (bit 7) bit is set and act accordingly. If the NAK_TIMEOUT bit is set, the controller can be directed either to continue trying this transaction (until it times out again) by clearing the NAK_TIMEOUT bit or to abort the transaction by flushing the FIFO before clearing the NAK_TIMEOUT bit.

If large blocks of data are being transferred, then the overhead of calling an interrupt service routine to load each packet can be avoided by using DMA.

15.3.8.2.2.2.3 Bulk OUT Error Handling: Host Mode

If the target wants to shut down the Bulk OUT pipe, it will send a STALL response. This is indicated by the RXSTALL bit of HOST_TXCSR register (bit 5) being set.

15.3.8.2.3 Interrupt Transfer: Host Mode

When the controller is operating as the host, interactions with an Interrupt endpoint on the USB peripheral device are handled in very much the same way as the equivalent Bulk transactions (described in previous sections).

The principal difference as far as operational steps are concerned is that the PROT field of HOST_RXTYPE and HOST_TXTYPE (bits 5-4) need to be set (binary value) to represent an Interrupt transaction. The required polling interval also needs to be set in the HOST_RXINTERVAL and HOST_TXINTERVAL registers.

15.3.8.2.4 Isochronous Transfer: Host Mode

Isochronous transfers are used when working with isochronous data. Isochronous transfers provide periodic, continuous communication between host and device.

An Isochronous IN transaction is used to transfer periodic data from the USB peripheral to the host.

15.3.8.2.4.1 Isochronous IN Transactions: Host Mode

The following optional features are available for use with an Rx endpoint used in Host mode to receive this data:

- Double packet buffering: When enabled, up to two packets can be stored in the FIFO on reception from the host. This allows that one packet can be received while another is being read. Double packet buffering is enabled by setting the DPB bit of RXFIFOSZ register (bit 4).
- AutoRequest: When the AutoRequest feature is enabled, the REQPKT bit of HOST_RXCSR (bit 5) will be automatically set when the RXPKTRDY bit is cleared. This only applies when the CPU is being used to service the endpoint. When using DMA, this bit field needs to be cleared to Zero. CPPI DMA has its own configuration registers that renders a similar task, USB0/1 Auto Req registers, that needs to be used to have a similar effect. For more information, see section on CPPI DMA.
- DMA: If DMA is enabled for the endpoint, a DMA request will be generated whenever the endpoint has a packet in its FIFO. This feature can be used to allow the DMA controller to unload packets from the FIFO without processor intervention. However, this feature is not particularly useful with isochronous endpoints because the packets transferred are often not maximum packet size.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

- When DMA is enabled, endpoint interrupt will not be generated for completion of packet reception. Endpoint interrupt will be generated only in the error conditions.

15.3.8.2.4.1.1 Isochronous IN Transfer Setup: Host

Before initiating an Isochronous IN Transactions in Host mode:

- The target function address needs to be set in the RXFUNCADDR register for the selected controller endpoint (RXFUNCADDR register is available for all endpoints from EP0 to EP4).
- The HOST_RXTYPE register for the endpoint that is to be used needs to be programmed as:
  - Operating speed in the SPEED bit field (bits 7 and 6).
  - Set 01 (binary value) in the PROT field for isochronous transfer.
  - Endpoint Number of the target device in RENDPN field. This is the endpoint number contained in the Rx endpoint descriptor returned by the target device during enumeration.
- The RXMAXP register for the controller endpoint must be written with the maximum packet size (in bytes) for the transfer. This value should be the same as the wMaxPacketSize field of the Standard Endpoint Descriptor for the target endpoint.
- The HOST_RXINTERVAL register needs to be written with the required transaction interval (usually one transaction per frame/microframe).
- The relevant interrupt enable bit in the INTRRXE register should be set (if an interrupt is required for this endpoint).
- The following bits of HOST_RXCSR register should be set as:
  - Clear AUTOCLEAR
  - Set the DMAEN bit (bit 13) to 1 if a DMA request is required for this endpoint.
  - Clear the DISNYET it (bit 12) to 0 to allow normal PING flow control. This will only affect High Speed transactions.
  - Clear DMAMODE bit (bit 11) to 0.
- If DMA is enabled, AUTOREQ register can be set for generating IN tokens automatically after receiving the data. Set the bit field RXn_AUTOREQ (where n is the endpoint number) with binary value 01 or 11. For detailed information on using CPPI DMA, consult related section within this document.

15.3.8.2.4.1.2 Isochronous IN Operation: Host Mode

The operation starts with the software setting REQPKT bit of HOST_RXCSR (bit 5). This causes the controller to send an IN token to the target.

When a packet is received, an interrupt is generated which the software may use to unload the packet from the FIFO and clear the RXPKTRDY bit in the HOST_RXCSR register (bit 0) in the same way as for a Bulk Rx endpoint. As the interrupt could occur almost any time within a frame(/microframe), the timing of FIFO unload requests will probably be irregular. If the data sink for the endpoint is going to some external hardware, it may be better to minimize the requirement for additional buffering by waiting until the end of each frame before unloading the FIFO. This can be done by using the SOF_PULSE signal from the controller to trigger the unloading of the data packet. The SOF_PULSE is generated once per frame(/microframe). The interrupts may still be used to clear the RXPKTRDY bit in HOST_RXCSR.

15.3.8.2.4.1.3 Isochronous IN Error Handling: Host Mode

If a CRC or bit-stuff error occurs during the reception of a packet, the packet will still be stored in the FIFO but the DATAERR_NAKTIMEOUT bit of HOST_RXCSR (bit 3) is set to indicate that the data may be corrupt.

Note: The number of USB packets sent in any microframe will depend on the amount of data to be transferred, and is indicated through the PIDs used for the individual packets. If the indicated numbers of packets have not been received by the end of a microframe, the INCOMPRX bit in the HOST_RXCSR register will be set to indicate that the data in the FIFO is incomplete. Equally, if a packet of the wrong data type is received, then the PID Error bit is the HOST_RXCSR register will be set. In each case, an interrupt will, however, still be generated to allow the data that has been received to be read from the FIFO.

Copyright © 2011, Texas Instruments Incorporated

15.3.8.2.4.2 Isochronous OUT Transactions: Host Mode

An Isochronous OUT transaction may be used to transfer periodic data from the host to the USB peripheral.

Following optional features are available for use with a Tx endpoint used in Host mode to transmit this data:

- Double packet buffering: When enabled, up to two packets can be stored in the FIFO awaiting transmission to the peripheral device. Double packet buffering is enabled by setting the DPB bit of TXFIFOSZ register (bit 4).

DMA: If DMA is enabled for the endpoint, a DMA request will be generated whenever the endpoint is able to accept another packet in its FIFO. This feature can be used to allow the DMA controller to load packets into the FIFO without processor intervention.

However, this feature is not particularly useful with isochronous endpoints because the packets transferred are often not maximum packet size.

When DMA is enabled and endpoint interrupt will not be generated for completion of packet reception. Endpoint interrupt will be generated only in the error conditions.

15.3.8.2.4.2.1 Isochronous OUT Transfer Setup: Host Mode

Before initiating any Isochronous OUT transactions:

- The target function address needs to be set in the TXFUNCADDR register for the selected controller endpoint (TXFUNCADDR register is available for all endpoints from EP0 to EP4).
- The HOST_TXTYPE register for the endpoint that is to be used needs to be programmed as:
  - Operating speed in the SPEED bit field (bits 7 and 6).
  - Set 01 (binary value) in the PROT field for isochronous transfer.
  - Endpoint Number of the target device in TENDPN field. This is the endpoint number contained in the OUT(Tx) endpoint descriptor returned by the target device during enumeration.
- The TXMAXP register for the controller endpoint must be written with the maximum packet size (in bytes) for the transfer. This value should be the same as the wMaxPacketSize field of the Standard Endpoint Descriptor for the target endpoint.
- The HOST_TXINTERVAL register needs to be written with the required transaction interval (usually one transaction per frame/microframe).
- The relevant interrupt enable bit in the INTRTXE register should be set (if an interrupt is required for this endpoint).
- The following bits of HOST_TXCSR register should be set as:
  - Set the MODE bit (bit 13) to 1 to ensure the FIFO is enabled (only necessary if the FIFO is shared with an Rx endpoint).
  - Set the DMAEN bit (bit 12) to 1 if a DMA request is required for this endpoint
  - The FRCDATATOG bit (bit 11) is ignored for isochronous transactions.
  - Set the DMAMODE bit (bit 10) to 1 when DMA is enabled.
    For more details in using DMA, consult CPPI DMA section within this document.

15.3.8.2.4.2.2 Isochronous OUT Transfer Operation: Host Mode

The operation starts when the software writes to the FIFO and sets TXPKTRDY bit of HOST_TXCSR (bit 0). This triggers the controller to send an OUT token followed by the first data packet from the FIFO.

An interrupt is generated whenever a packet is sent and the software may use this interrupt to load the next packet into the FIFO and set the TXPKTRDY bit in the HOST_TXCSR register (bit 0) in the same way as for a Bulk Tx endpoint. As the interrupt could occur almost any time within a frame, depending on when the host has scheduled the transaction, this may result in irregular timing of FIFO load requests. If

DRAFT ONLY

the data source for the endpoint is coming from some external hardware, it may be more convenient to wait until the end of each frame before loading the FIFO as this will minimize the requirement for additional buffering. This can be done by using the SOF_PULSE signal from the controller to trigger the loading of the next data packet. The SOF_PULSE is generated once per frame(/microframe). The interrupts may still be used to set the TXPKTRDY bit in HOST_TXCSR.

15.3.9 Communications Port Programming Interface (CPPI) 4.1 DMA

The CPPI DMA module supports the transmission and reception of USB packets. The CPPI DMA is designed to facilitate the segmentation and reassembly of CPPI compliant packets to/from smaller data blocks that are natively compatible with the specific requirements of each networking port. Multiple Tx and Rx channels are provided for all endpoints (excluding endpoint 0) within the DMA allowing multiple segmentation or reassembly operations to be effectively performed in parallel (but not actually simultaneously). The DMA controller maintains state information for each of the ports/channels which allows packet segmentation and reassembly operations to be time division multiplexed between channels in order to share the underlying DMA hardware. A DMA scheduler is used to control the ordering and rate at which this multiplexing occurs.

The CPPI (version 4.1) DMA controller sub-module is a common 15 port DMA controller. It supports 15 Tx and 15 Rx channels and each port attaches to the associated endpoint in the controller. Port 1 maps to endpoint 1 and Port 2 maps to endpoint 2 and so on with Port 15 mapped to endpoint 15; endpoint 0 can not utilize the DMA and the firmware is responsible to load or offload the endpoint 0 FIFO via CPU.

15.3.9.1 CPPI Terminology

Host — The host is an intelligent system resource that configures and manages each communications control module. The host is responsible for allocating memory, initializing all data structures, and responding to port interrupts.

Main Memory — The area of data storage managed by the CPU. The CPPI DMA (CDMA) reads and writes CPPI packets from and to main memory. This memory can exist internal or external from the device.

Queue Manager (QM) — The QM is responsible for accelerating management of a variety of Packet Queues and Free Descriptor / Buffer Queues. It provides status indications to the CDMA Scheduler when queues are empty or full.

CPPI DMA (CDMA) — The CDMA is responsible for transferring data between the CPPI FIFO and Main Memory. It acquires free Buffer Descriptor from the QM (Receive Submit Queue) for storage of received data, posts received packets pointers to the Receive Completion Queue, transmits packets stored on the Transmit Submit Queue (Transmit Queue) , and posts completed transmit packets to the Transmit Completion Queue.

CDMA Scheduler (CDMAS) — The CDMAS is responsible for scheduling CDMA transmit and receive operations. It uses Queue Indicators from the QM and the CDMA to determine the types of operations to schedule.

CPPI FIFO — The CPPI FIFO provides FIFO interfaces (for each of the 15 transmit and 15 receive endpoints).

Transfer DMA (XDMA) — The XDMA receives DMA requests from the Mentor USB 2.0 Core and initiates DMAs to the CPPI FIFO.

Endpoint FIFOs — The Endpoint FIFOs are the USB packet storage elements used by the Mentor USB 2.0 Core for packet transmission or reception. The XDMA transfers data between the CPPI FIFO and the Endpoint FIFOs for transmit operations and between the Endpoint FIFOs and the CPPI FIFO for receive operations.

Port — A port is the communications module (peripheral hardware) that contains the control logic for Direct Memory Access for a single transmit/receive interface or set of interfaces. Each port may have multiple communication channels that transfer data using homogenous or heterogeneous protocols. A port is usually subdivided into transmit and receive pairs which are independent of each other. Each endpoint, excluding endpoint 0, has its own dedicated port.

Channel — A channel refers to the sub-division of information (flows) that is transported across ports. Each channel has associated state information. Channels are used to segregate information flows based on the protocol used, scheduling requirements (example: CBR, VBR, ABR), or concurrency requirements (that is, blocking avoidance). All fifteen ports per USB Module have dedicated single channels, channel 0, associated for their use in a USB application.

Copyright © 2011, Texas Instruments Incorporated

Data Buffer — A data buffer is a single data structure that contains payload information for transmission to or reception from a port. A data buffer is a byte aligned contiguous block of memory used to store packet payload data. A data buffer may hold any portion of a packet and may be linked together (via descriptors) with other buffers to form packets. Data buffers may be allocated anywhere within the 32-bit memory space. The Buffer Length field of the packet descriptor indicates the number of valid data bytes in the buffer. There may be from 1 to 4M-1 valid data bytes in each buffer.

Host Buffer Descriptor (Buffer Descriptor) — A buffer descriptor is a single data structure that contains information about one or more data buffers. This type of descriptor is required when more than one descriptor is needed to define an entire packet, i.e., it either defines the middle of a packet or end of a packet.

Start of Packet (SOP) — Packet along side Buffer Descriptors are used to hold information about Packets. When multiple Descriptors are used to hold a single packet information or a single Descriptor is used to hold a single packet information, the first descriptor is referred to as a Packet Descriptor which is also Start-of-Packet Descriptor.

Host Packet Descriptor (Packet Descriptor) — A packet descriptor is another name for the first buffer descriptor within a packet. Some fields within a data buffer descriptor are only valid when it is a packet descriptor including the tags, packet length, packet type, and flags. This type of descriptor is always used to define a packet since it provides packet level information that is useful to both the ports and the Host in order to properly process the packet. It is the only descriptor used when single descriptor solely defines a packet. When multiple descriptors are needed to define a packet, the packet descriptor is the first descriptor used to define a packet.

Free Descriptor/Buffer Queue — A free descriptor/buffer queue is a hardware managed list of available descriptors with pre-linked empty buffers that are to be used by the receive ports for host type descriptors. Free Descriptor/Buffer Queues are implemented by the Queue Manager.

Teardown Descriptor — Teardown Descriptor is a special structure which is not used to describe either a packet or a buffer but is instead used to describe the completion of a channel halt and teardown event. Channel teardown is an important function because it ensures that when a connection is no longer needed that the hardware can be reliably halted and any remaining packets which had not yet been transmitted can be reclaimed by the Host without the possibility of losing buffer or descriptor references (which results in a memory leak).

Packet Queue — A packet queue is hardware managed list of valid (i.e. populated) packet descriptors that is used for forwarding a packet from one entity to another for any number of purposes.
NOTE: All descriptors (regardless of type) must be allocated at addresses that are naturally aligned to the smallest power of 2 that is equal to or greater than the descriptor size.

15.3.9.2 Data Structures

Two data structures are mainly used to identify data buffers used by packet and buffer descriptors. A third Descriptor, Teardown Descriptor, exists. The purpose of this Descriptor is a channel halt and teardown event. Each of these Descriptor layouts as well as bit fields are shown below.

15.3.9.2.1 Host Packet Descriptor/ Packet Descriptor (SOP Descriptor)

Descriptors are designed to be used when USB like application requires support for true, unlimited fragment count scatter/gather type operations. The Packet Descriptor is the first descriptor on multiple descriptors setup or the only descriptor in a single descriptors setup. The Packet Descriptor contains the following information:

- Indicator which identifies the descriptor as a packet descriptor (always 10h
- Source and destination tags (reserved)
- Packet type
- Packet length
- Protocol specific region size
- Protocol specific control/statusbits
- Pointer to the first valid byte in the SOP data buffer

Copyright © 2011, Texas Instruments Incorporated

- Length of the SOP data buffer
- Pointer to the next buffer descriptor in the

Packet descriptors can vary in size by design of their defined fields from 32 bytes up to 104 bytes. Within this range, packet descriptors always contain 32 bytes of required information and may also contain 8 bytes of software specific tagging information and up to 64 bytes (indicated in 4 byte increments) of protocol specific information. How much protocol specific information (and therefore the allocated size of the descriptors) is application dependent. Port will make use of the first 32 bytes only.

From a general USB use perspective, a 32-byte descriptor size is suffix and the use of this size is expected for a normal USB usage.

The packet descriptor layout is shown in Figure 15-13 and described within Table 15-9 through Table 15-16.

Figure 15-13. Packet Descriptor Layout

Table 15-9. Packet Descriptor Word 0 (PD0) Bit Field Descriptions

Bits	Field Name	Description
31-27	Descriptor type	The host packet descriptor type is 16 decimal (10h). The CPU initializes this field.
26-22	Protocol-specific valid word count	This field indicates the valid number of 32-bit words in the protocol-specific region. The CPU initializes this field. This is encoded in increments of 4 bytes as: 0 = 0 byte 1 = 4 bytes ... 16 = 64 bytes 17-31 = Reserved
21-0	Packet length	The length of the packet in bytes. If the packet length is less than the sum of the buffer lengths, then the packet data will be truncated. A packet length greater than the sum of the buffers is an error. The valid range for the packet length is 0 to (4M - 1) bytes. The CPU initializes this field for transmitted packets; the DMA overwrites this field on packet reception.

Copyright © 2011, Texas Instruments Incorporated

Table 15-10. Packet Descriptor Word 1 (PD1) Bit Field Descriptions

Bits	Field Name	Description
31-27	Source Tag; Port #	This field indicates the port number (0-31) from which the packet originated. The DMA overwrites this field on packet reception. This is the RX Endpoint number from which the packet originated.
26-21	Source Tag; Channel #	This field indicates the channel number within the port from which the packet originated. The DMA overwrites this field on packet reception. This field is always 0-67.
20-16	Source Tag: Sub-channel #	This field indicates the sub-channel number (0-31) within the channel from which the packet originated. The DMA overwrites this field on packet reception. This field is always 0.
15-0	Destination Tag	This field is application-specific. This field is always 0.

Table 15-11. Packet Descriptor Word 2 (PD2) Bit Field Descriptions

Bits	Field Name	Description
31	Packet error	This bit indicates if an error occurred during reception of this packet (0 = no error occurred; 1 = error occurred). The DMA overwrites t his field on packet reception. Additional information about different errors may be encoded in the protocol specific fields in the descriptor.
30-26		This field indicates the type of this packet. The CPU initializes this field for transmitted packets; the DMA overwrites this field on packet reception. This field is encoded as: 5 = USB 8-31 = Reserved
25-20	Reserved	Reserved
19	Zero-length packet indicator	If a zero-length USB packet is received, the XDMA will send the CDMA a data block with a byte count of 0 and this bit is set. The CDMA will then perform normal EOP termination of the packet without transferring data. For transmit, if a packet has this bit set, the XDMA will ignore the CPPI packet size and send a zero-length packet to the USB controller.
18-16	Protocol-specific	This field contains protocol-specific flags/information that can be assigned based on the packet type. Not used for USB.
15	Return policy	This field indicates the return policy for this packet. The CPU initializes this field. 0 = Entire packet (still linked together) should be returned to the queue specified in bits 13-0. 1 = Each buffer should be returned to the queue specified in bits 13-0 of Word 2 in their respective descriptors. The Tx DMA will return each buffer in sequence.
14	On-chip	This field indicates whether or not this descriptor is in a region which is in on-chip memory space (1) or in external memory (0).
31-12	Packet return queue mgr #	This field indicates which queue manager in the system the descriptor is to be returned to after transmission is complete. This field is not altered by the DMA during transmissionor reception and is initialized by the CPU. There is only one queue manager in the USB HS/FS device controller. This field must always be 0.
11-0	Packet return queue #	This field indicates the queue number within the selected queue manager that the descriptor is to be returned to after transmission is complete. This field is not altered by the DMA during transmission or reception and is initialized by the CPU.

Table 15-12. Packet Descriptor Word 3 (PD3) Bit Field Descriptions

Bits	Field Name	Description
31-22	Reserved	Reserved
21-0	Buffer 0 length	The buffer length field indicates how many valid data bytes are in the buffer. The CPU initializes this field for transmitted packets; the DMA overwrites this field on packet reception.

Table 15-13. Packet Descriptor Word 4 (PD4) Bit Field Descriptions

Bits	Field Name	Description
31-0	Buffer 0 pointer	The buffer pointer is the byte-aligned memory address of the buffer associated with the buffer descriptor. The CPU initializes this field for transmitted packets; the DMA overwrites this field on packet reception.

Table 15-14. Packet Descriptor Word 5 (PD5) Bit Field Descriptions

Bits	Field Name	Description
31-0	Next descriptor pointer	The 32-bit word aligned memory address of the next buffer descriptor in the packet. If the value of this pointer is zero, then the current buffer is the last buffer in the packet. The CPU initializes this field for transmitted packets; the DMA overwrites this field on packet reception.

Table 15-15. Packet Descriptor Word 6 (PD6) Bit Field Descriptions

Bits	Field Name	Description
31-22	Reserved	Reserved
21-0	Original buffer 0 length	The buffer length field indicates the original size of the buffer in bytes. This value is not overwritten during reception. This value is read by the Rx DMA to determine the actual buffer size as allocated by the CPU at initialization. Since the buffer length in Word 3 is overwritten by the Rx port during reception, this field is necessary to permanently store the buffer size information.

Table 15-16. Packet Descriptor Word 7 (PD7) Bit Field Descriptions

Bits	Field Name	Description
31-22	Reserved	Reserved
21-0	Original buffer 0 pointer	The buffer pointer is the byte-aligned memory address of the buffer associated with the buffer descriptor. This value is not overwritten during reception. This value is read by the Rx DMA to determine the actual buffer location as allocated by the CPU at initialization. Since the buffer pointer in Word 4 is overwritten by the Rx port during reception, this field is necessary to permanently store the buffer pointer information.

15.3.9.2.2 Host Buffer Descriptor/Buffer Descriptor (BD)

The buffer descriptor is identical in size and organization to a Packet Descriptor but does not include valid information in the packet level fields and does not include a populated region for protocol specific information. The packet level fields are not needed since the SOP descriptor contains this information and additional copy of this data is not needed/necessary.

Host buffer descriptors are designed to be linked onto a host packet descriptor or another host buffer descriptor to provide support for unlimited scatter / gather type operations. Host buffer descriptors provide information about a single corresponding data buffer. Every host buffer descriptor stores the following information:

- Pointer to the first valid byte in the data
- Length of the data buffer
- Pointer to the next buffer descriptor in the packet

Buffer descriptors always contain 32 bytes of required information. Since it is a requirement that it is possible to convert a descriptor between a Buffer Descriptor and a Packet Descriptor (by filling in the appropriate fields) in practice, Buffer Descriptors will be allocated using the same sizes as Packet Descriptors. In addition, since the 5 LSBs of the Descriptor Pointers are used in CPPI 4.1 for the purpose of indicating the length of the descriptor, the minimum size of a descriptor is always 32 bytes

31-0	Next description pointer	The 32-bit word aligned memory address of the next buffer descriptor in the packet. If the value of this pointer is zero, then the current descriptor is the last descriptor in the packet. The CPU initializes this field for transmitted packets. The DMA overwrites this field upon packet reception.

Table 15-23. Buffer Descriptor Word 6 (BD6) Bit Field Descriptions

Bits	Field Name	Description
31-22	Reserved	Reserved
21-0	Original buffer 0 length	The buffer length field indicates the original size of the buffer in bytes. This value is not overwritten during reception. This value is read by the Rx DMA to determine the actual buffer size as allocated by the CPU at initialization. Since the buffer length in Word 3 is overwritten by the Rx port during reception, this field is necessary to permanently store the buffer size information.

Table 15-24. Buffer Descriptor Word 7 (BD7) Bit Field Descriptions

Bits	Field Name	Description
31-0	Original buffer 0 pointer	The buffer pointer is the byte-aligned memory address of the buffer associated with the buffer descriptor. This value is not overwritten during reception. This value is read by the Rx DMA to determine the actual buffer location as allocated by the CPU at initialization. Since the buffer pointer in Word 4 is overwritten by the Rx port during reception, this field is necessary to permanently store the buffer pointer information.

15.3.9.2.3 Teardown Descriptor

The Teardown Descriptor is not like the packet or buffer descriptors since it is not used to describe either a packet or a buffer. The teardown descriptor is always 32 bytes long and is comprised of 4 bytes of actual teardown information and 28 bytes of pad. The teardown descriptor layout and associated bit field descriptions are shown in the Figure below and Tables that follows. Since the 5 LSBs of the descriptor pointers are used in CPPI 4.1 for the purpose of indicating the length of the descriptor, the minimum size of a descriptor is 32 bytes.

The teardown descriptor is used to describe a channel halt and teardown event. Channel teardown ensures that when a connection is no longer needed that the hardware can be reliably halted and any remaining packets which had not yet been transmitted can be reclaimed by the host without the possibility of losing buffer or descriptor references (which results in a memory leak).

Theteardown descriptor contains the following information:

- Indicator which identifies the descriptor as a teardown packet descriptor
- DMA controller number where teardown
- Channel number within DMA where teardown occurred
- Indicator of whether this teardown was for the Tx or Rx channel

Figure 15-15. Teardown Descriptor Layout

Table 15-25. Teardown Descriptor Word 0 Bit Field Descriptions

Bits	Field Name	Description
31-27	Descriptor type	The teardown descriptor type is 19 decimal (13h)
26-17	Reserved	Reserved
16	TX_RX	Indicates whether teardown is a TX (0) or RX (1).
15-10	DMA number	Indicates the DMA number for this teardown.
9-6	Reserved	Reserved
5-0	Channel number	Indicates the channel number within the DMA that was torn down.

Table 15-26. Teardown Descriptor Words 1 to 7 Bit Field Descriptions

Bits	Field Name	Description
31-0	Reserved	Reserved

Teardown operation of an endpoint requires three operations. The teardown register in the CPPI DMA must be written, the corresponding endpoint bit in TEARDOWN of the USB module must be set, and the FlushFIFO bit in the Mentor USB controller Tx/RxCSR register must be set.

The following is the Transmit teardown procedure highlighting the steps required to be followed:

1. Set the TX_TEARDOWN bit in the CPPI DMA TX channel n global configuration register (TXGCRn).
2. Set the appropriate TX_TDOWN bit in the USBOTG controller's USB teardown register (TEARDOWN). Write Tx Endpoint Number to teardown to TEARDOWN[TX_TDOWN] field.
3. Check if the teardown descriptor has been received on the teardown queue: The completion queue (see Queue Assignment table) is usually used as the Teardown queue when the Teardown descriptor has been received, the descriptor address will be loaded onto CTRLD[Completion Queue #] register:
   (a) If not, go to step 2
   (b) If so, go to step 4
4. Set the appropriate TX_TDOWN bit in the USBOTG controller's USB teardown register (TEARDOWN). Set the bit corresponding to the Channel Number within TEARDOWN[TX_TDOWN] field.
5. Flush the TX FIFO in the Mentor OTG core: Set PERI_TXCSR[FLUSHFIFO] for the corresponding Endpoint.
6. Re-enable the Tx DMA channel.
   (a) Clear TXGCRn[TX_TEARDOWN and TX_ENABLE] bit.
   (b) Set TXGCRn[TX_ENABLE] bit.

15.3.9.3 Queue Manager

The queue manager (QM) is a hardware module that is responsible for accelerating management of the queues, i.e. queues are maintained within a queue manager module. Packets are added to a queue by writing the 32-bit descriptor address to a particular memory mapped location in the queue manager module. Packets are de-queued by reading the same location for that particular queue. A single queue manager exists within the device and handles all available 156 queues within the USB subsystem

Descriptors are queued onto a logical queue (pushed) by writing the descriptor pointer to the Queue N Register D. When the Queue N Register D is written, this kicks off the queue manager causing it to add the descriptor to the tail of queue.

The QM keeps track of the order of the descriptors pushed within a queue or the linking status of the descriptors. To accomplish this linking status, QM will first resolve the 32-bit descriptor pointer into a 16-bit index which is used for linking a queue pointer purposes. Once the address to index computation is performed, i.e., the physical index information is determined, the QM will link that descriptor onto the descriptor chain that is maintained for that logical queue by writing the linking information out to a linking RAM which is external to the queue manager. More on linking RAM discussion would follow in latter sections. The QM will also update the queue tail pointers appropriately. Since logical queues within the queue manager are maintained using linked lists, queues cannot become full and no check for fullness is required before queuing a packet descriptor.

15.3.9.3.1 Queue Types

Several types of queues exist (a total of 156 queues) within the CPPI 4.1 DMA. Regardless of the type of queue, queues are used to hold pointers to Packet or Buffer Descriptors while they are being passed between the Host and / or any of the ports in the system. All queues are maintained within the single Queue Manager module.

The following types of Queues exist:

- Free descriptor queue (unassigned to specific endpoint but assigned to specific endpoint type; receive endpoints – can be used as a receive submit queue)
- Transmit submit queue
- Transmit completion (return) queue
- Receive completion (return) queue
- Teardown queue

Dedicated queues exist where one or more queues are assigned for the use of a single endpoint and non-dedicated queues exist where no specific queue assignment to an endpoint is required (but pertains to receive endpoints only). Transmit endpoints are not allowed to use free descriptor queues.

Dedicated queues exist for each specific endpoint use and non-dedicated queues exist that can be used by any/all receive endpoints. Three queues are reserved for each endpoint/port for transmit actions with two of the three queues being transmit submit queues while the remaining queue is used as a completion/return queue. For receive actions, the only dedicated queues are completion/return queues; one queue is assigned/reserved for each receive endpoint. 32 free descriptor queues that do not have dedicated endpoint-queue assignment exist and these queues are used to service any receive endpoint as receive submit queues.

Table 15-27 displays queue-endpoint assignments.

15.3.9.3.2 Free Descriptor Queue (Receive Submit Queue)

Receive endpoints/channels use queues, referred to as free descriptor queues, or receive submit queues, to forward completed receive packets to the host. The entries on the free descriptor queues have pre-attached empty buffers whose size and location are described in the original buffer information fields in the descriptor. The host is required to allocate both the descriptor and buffer and pre-link them prior to adding (submitting) a descriptor to one of the available free descriptor queue. The first 32 queues (queue 0 up to queue 31) are reserved for all 30 USB0/1 (endpoints 1 to 15 of each USB module) receive endpoints/channels to handle incoming packets to the device.

15.3.9.3.3 Transmit Submit Queue

Transmit ports use packet queues, referred to as transmit submit queues, to store the packets that are waiting to be transmitted. Each transmit endpoint has dedicated queues (2 queues per port) that are reserved exclusively for a use by a single endpoint. Multiple queues per port/channel are allocated to facilitate quality of service (QoS) for applications that require QoS. The first 30 queues, queue 32 up to queue 61, are allocated for USB0 transmit endpoints 1 to 15 with two queues per endpoint.queues 62 up to queue 91, are allocated for transmit USB1 endpoints 1 to 15.

15.3.9.3.4 Transmit Completion (Return) Queue

Transmit ports use packet queues, referred to as "transmit completion queues, to return packet descriptors to the host after packets have been transmitted. A singe queue is reserved to be used by a single transmit endpoint. Application s/w needs to insure that the right set of queues is used to return the Descriptors after the completion of a packet transmission based on the endpoint number used. For USB0 transmit endpoints 1 to 15 Queues 92 up to queue 106 are reserved/assigned for use as a completion queue respectively. Similarly for USB1 transmit endpoints 1 to 15, queues 107 up to queue 121 is used as completion queue, respectively.

Transmit Completion Queues are also used to return packet Descriptors when performing a Transmit channel teardown operation.

15.3.9.3.5 Receive Completion (Return) Queue

Receive ports use packet queues, referred to as receive completion queues, to return packet descriptors to the port after packets have been received. A singe queue is reserved to be used by a single receive endpoint. Application s/w needs to insure that the right set of queues is used to return the descriptors after the completion of a packet reception based on the endpoint number used. For USB0 receive endpoints 1 to 15 queues 122 up to queue 136 are reserved/assigned for use as a receive completion queue respectively. Similarly for USB1 receive endpoints 1 to 15, queues 137 up to queue 151 is used as completion queue respectively.

Receive channel teardown is not necessary for receive transactions and no channel teardown information nor resource is available

15.3.9.3.6 Diverting Queue Packets from one Queue to Another

The host can move the entire contents of one queue to another queue by writing the source queue number and the destination queue number to the Queue Diversion register. When diverting packets, the descriptors are pushed onto the tail of the destination queue.

15.3.9.3.7 Teardown Queue

Teardown queue

15.3.9.4 Memory Regions and Linking RAM

In addition to allocating buffer for raw data and memory for Descriptors, the host is responsible for allocating additional memory for exclusive use of the CPPI DMA Queue Manager to be used as a scratch PAD RAM. The queue manager uses this memory to manage states of descriptors submitted within the submit queues. In other words, this memory needs not to be managed by the user software and firmware

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

responsibility lies only for allocation/reserving a chunk of memory for the use of the queue manager. The allocated memory can be a single block of memory that is contiguous or two blocks of memory that are not contiguous. These two blocks of memory are referred to as a Linking RAM Regions and should not be confused with memory regions that are used to store descriptors. That is, the use of the term *region* should be used in the context of its use.

To accomplish the linking of submitted descriptors, the queue manager will first resolve the 32-bit descriptor pointer into a 16-bit index which is used for linking and queue pointer purposes. Once the physical index information is determined, the queue manager will link that descriptor onto the descriptor chain that is maintained for that logical queue by writing the linking information out to a linking RAM which is external to the queue manager. The queue manager will also update the queue tail pointer appropriately. Since logical queues within the queue manager are maintained using linked lists, queues cannot become full and no check for fullness is required before queuing a packet descriptor.

The actual physical size of the Linking RAM region(s) to be allocated depends on the total number of descriptors defined within all memory regions. A minimum of four bytes of memory needs to be allocated for each Descriptor defined within all 16 memory regions.

The queue manager has the capability of managing up to 16 memory regions. These memory regions are used to store descriptors of variable sizes. The total number of descriptors that can be managed by the queue manager should not exceed 64K. Each memory region has descriptors of one configurable size, that is, descriptors with different sizes cannot be housed within a single memory region. These 64K descriptors are referenced internally in the queue manager by a 16-bit quantity index.

The information about the Linking RAM regions and the size that are allocated is communicated to the CPPI DMA via three registers dedicated for this purpose. Two of the three registers are used to store the 32-bit aligned start addresses of the Linking RAM regions. The remaining one register is used to store the size of the first Linking RAM. The linking RAM size value stored here is the number of descriptors that is to be managed by the queue manager within that region not the physical size of the buffer, which is four times the number of descriptors.

Note that application is not required to use both linking RAM regions, if the size of the Linking RAM for the first region is large enough to accommodate all descriptors defined. No linking RAM size register for linking RAM region 2 exists. The size of the second linking RAM, when used, is indirectly computed from the total number of descriptors defined less the number of descriptors managed by the first linking RAM

Figure 15-16 displays the relationship between several memory regions and linking RAM.

Figure 15-16. Relationship Between Memory Regions and Linking RAM

15.3.9.5 Zero Length Packets

A special case is the handling of null packets with the CPPI 4.1 compliant DMA controller. Upon receiving a zero length USB packet, the XFER DMA will send a data block to the DMA controller with byte count of zero and the zero byte packet bit of INFO Word 2 set. The DMA controller will then perform normal End of Packet termination of the packet, without transferring data.

If a zero-length USB packet is received, the XDMA will send the CDMA a data block with a byte count of 0 and this bit set. The CDMA will then perform normal EOP termination of the packet without transferring data. For transmit, if a packet has this bit set, the XDMA will ignore the CPPI packet size and send a zero-length packet to the USB controller.

15.3.9.6 CPPI DMA Scheduler

The CPPI DMA scheduler is responsible for controlling the rate and order between the different Tx and Rx threads/transfers that are provided in the CPPI DMA controller. The scheduler table RAM exists within the scheduler.

The DMA controller maintains state information for each of the channels which allows packet segmentation and reassembly operations to be time division multiplexed between channels in order to share the underlying DMA hardware. A DMA scheduler is used to control the ordering and rate at which this multiplexing occurs.

15.3.9.6.1 CPPI DMA Scheduler Operation

Once the scheduler is enabled it will begin processing the entries in the table. When appropriate the scheduler will pass credits to the DMA controller to perform a Tx or Rx operation. The operation of the DMA controller is as follows:

1. After the DMA scheduler is enabled it begins with the table index set to 0.
2. The scheduler reads the entry pointed to by the index and checks to see if the channel in question is currently in a state where a DMA operation can be accepted.
   (a) The DMA channel must be enabled AND
   (b) The CPPI FIFO that the channel talks to has free space on TX (FIFO full signal is not asserted) or a valid block on Rx (FIFO empty signal is not asserted)
3. If the DMA channel is capable of processing a credit to transfer a block, the DMA scheduler will issue that credit via the DMA scheduling interface which is a point to point connection between the DMA Scheduler and the DMA Controller.
   (a) The DMA controller may not be ready to accept the credit immediately and is provided a sched_ready signal which is used to stall the scheduler until it can accept the credit. The DMA controller only asserts the sched_ready signal when it is in the IDLE state.
   (b) Once a credit has been accepted (indicated by sched_req and sched_ready both asserted), the scheduler will increment the index to the next entry and will start again at step 2.
4. If the channel in question is not currently capable of processing a credit, the scheduler will increment the index in the scheduler table to the next entry and will start at step 2.
5. Note that when the scheduler attempts to increment its index, to the value programmed in the table size register, the index will be reset to 0.

15.3.9.6.1.1 CPPI DMA Scheduler Initialization

Before the scheduler can be used, the host is required to initialize and enable the block. This initialization is performed as follows:

1. The Host initializes entries within an internal memory array in the scheduler. This array contains up to 256 entries (4 entries per table word n where n=0-63) and each entry consists of a DMA channel number and a bit indicating if this is a Tx or Rx opportunity. These entries represent both the order and frequency that various Tx and Rx channels will be processed. A table size of 256 entries allows channel bandwidth to be allocated with a maximum precision of 1/256th of the total DMA bandwidth. The more entries that are present for a given channel, the bigger the slice of the bandwidth that channel will be given. Larger tables can be accommodated to allow for more precision. This array can

Copyright © 2011, Texas Instruments Incorporated

only be written by the Host, it cannot be read.

2. If the application does not need to use the entire 256 entries, firmware can initialize the portion of the 256 entries and indicate the size of the entries used by writing onto an internal register in the scheduler which sets the actual size of the array (it can be less than 256 entries).
3. The host writes an internal register bit to enable the scheduler. The scheduler is not required to be disabled in order to change the scheduler array contents.

15.3.9.6.1.2 CPPI DMA Scheduler Programming Examples

Consider a three endpoints use on a system with the following configurations: EP1-Tx, EP2-Rx, and EP2-Tx. Two assumptions are considered:

Case 1: Assume that you would like to service each enabled endpoints (EP1-Tx, EP2-Rx, and EP2-Tx) with equal priority.

The scheduler handles the rate at which an endpoint is serviced by the number of credits programmed (entries) for that particular endpoint within the scheduler Table Words. The scheduler has up to 256 credits that it can grant and for this example the user can configure the number of entries/credits to be anywhere from 3 to 256 with a set of 3 entries.

However, the optimum and direct programming for this scenario would be programming only the first three entries of the scheduler via scheduler Table WORD[0]. Since this case expects the Scheduler to use only the first three entries, you communicate that by programming DMA_SCHED_CTRL.LAST_ENTRY with 2 (that is, 3 -1). The Enabled Endpoint numbers and the data transfer direction is then communicated by programming the first three entries of WORD[0] (ENTRY0_CHANNEL = 1: ENTRY0_RXTX = 0; ENTRY1_CHANNEL = 2: ENTRY1_RXTX = 1;ENTRY2_CHANNEL = 2: ENTRY2_RXTX = 0). With this programming, the Scheduler will only service the first three entries in a round-robin fashion, checking each credited endpoint for transfer one after the other, and servicing the endpoint that has data to transfer.

Case 2: Enabled endpoint EP1-Tx is serviced at twice the rate as the other enabled endpoints (EP2-Rx and EP2-Tx).

The number of entries/credit that has to be awarded to EP1-Tx has to be twice as much of the others. Four entries/credits would suffix to satisfy our requirement with two credits for EP1-Tx, one credit for EP2-Rx, and one credit for EP2-Tx. This requirement is satisfied by allocating any two of the four entries to EP1-Tx endpoint. Again for this example, scheduler Table WORD[0] would suffice since it can handle the first 4 entries. Even though several scenarios exist to programming the order of service for this case, one scenario would be to allow servicing EP1-Tx to back-to-back followed by the other enabled endpoints. Program DMA_SCHED_CTRL.LAST_ENTRY with 3 (that is, 4 -1). Program WORD[0] (ENTRY0_CHANNEL = 1: ENTRY0_RXTX = 0; ENTRY1_CHANNEL = 1: ENTRY1_RXTX = 0; ENTRY2_CHANNEL = 2: ENTRY2_RXTX = 1; ENTRY3_CHANNEL = 2: ENTRY3_RXTX = 0).

15.3.9.7 CPPI DMA State Registers

The port must store and maintain state information for each transmit and receive port/channel. The state information is referred to as the Tx DMA State and Rx DMA State.

15.3.9.7.1 Transmit DMA State Registers

The Tx DMA State is a combination of control fields and protocol specific port scratchpad space used to manipulate data structures and transmit packets. Each transmit channel has two queues. Each queue has a one head descriptor pointer and one completion pointer. There are thirty Tx DMA State registers; one for each port/channel.

The following information is stored in the Tx DMA State:

- Tx Queue Head Descriptor Pointer(s)
- Tx Completion Pointer(s)
- Protocol specific control/status (port scratchpad)

Copyright © 2011, Texas Instruments Incorporated

15.3.9.7.2 Receive DMA State Registers

The Rx DMA State is a combination of control fields and protocol specific port scratchpad space used to manipulate data structures in order to receive packets. Each receive channel has only one queue. Each channel queue has one head descriptor pointer and one completion pointer. There are thirty Rx DMA State registers; one for each port/channel.

The following information is stored in the Rx DMA State:

- Rx Queue Head Descriptor Pointer
- Rx Queue Completion Pointer
- Rx Buffer Offset

15.3.9.8 CPPI DMA Protocols Supported

Four different type of DMA transfers are supported by the CPPI 4.1 DMA; Transparent, RNDIS, Generic RNDIS, and Linux CDC. The following sections will outline the details on these DMA transfer types.

15.3.9.8.1 Transparent DMA Transfer

Transparent Mode DMA operation is the default DMA mode where DMA interrupt is generated whenever a DMA packet is transferred. In the transparent mode, DMA packet size cannot be greater than USB MaxPktSize for the endpoint. This transfer type is ideal for transfer (not packet) sizes that are less than a max packet size.

15.3.9.8.1.1 Transparent DMA Transfer Setup

The following will configure all 30 ports/channels for Transparent DMA Transfer type.

Make sure that RNDIS Mode is disabled globally. This allows the application to configure the CPPI DMA protocol in use to be configured per endpoint need. To disable RNDIS operation, clear RNDIS bit in the USB Control Registers corresponding to the USB Module (default setting), i.e., CTRL0[RNDIS]=0 and CTRL1[RNDIS]=0.

Configure the USB0/1 Tx/Rx DMA Mode Registers (USB0/1 TX(RX)MODE0/1) for the Endpoint field in use is programmed for Transparent Mode, i.e., TXMODE0/1[TXn_MODE] = 00b and RXMODE0/1[RXn_MODE] = 00b.

15.3.9.8.2 RNDIS DMA Transfer

RNDIS mode DMA is used for large transfers (i.e., total data size to be transferred is greater than USB MaxPktSize where the MzxPktSize is a multiple of 64 bytes) that requires multiple USB packets. This is accomplished by breaking the larger packet into smaller packets, where each packet size being USB MaxPktSize except the last packet where its size is less than USB MaxPktSize, including zero bytes. This implies that multiple USB packets of MaxPktSize will be received and transferred together as a single large DMA transfer and the DMA interrupt is generated only at the end of the complete reception of DMA transfer. The protocol defines the end of the complete transfer by receiving a short USB packet (smaller than USB MaxPktSize as mentioned in USB specification 2.0). If the DMA packet size is an exact multiple of USB MaxPktSize, the DMA controller waits for a zero byte packet at the end of complete transfer to signify the completion of the transfer.

NOTE: RNDIS Mode DMA is supported only when USB MaxPktSize is an integral multiple of 64 bytes.

15.3.9.8.2.1 RNDIS DMA Transfer Setup

If all endpoints in use are desired to operate in RNDIS mode, it is only suffix to configure RNDIS DMA operation in RNDIS mode at the global level and application can ignore individual endpoint DMA mode configuration. This is achieved by programming CTRLR0/1[RNDIS] with a ‘1.’

However if DMA mode is required to be configured at the endpoint level, it is required to disable the use of RNDIS at the global level, this is achieved by clearing RNDIS bit field (CTRLR0/1[RNDIS]=0), since global configuration over-rides endpoint configuration.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

To configure RNDIS DMA mode use, configure the field that correspond to the USB module endpoint using the corresponding USB0/1 TX(RX) Mode Register, i.e., TXMODE0/1[TXn_MODE] = 01b and RXMODE0/1[RXn_MODE] = 01b

15.3.9.8.3 Generic RNDIS DMA Transfer

Generic RNDIS DMA transfer mode is identical to the normal RNDIS mode in nearly all respects, except for the exception case where the last packet of the transfer can either be a short packet or the MaxPktSize. When the last packet size is equal to the MaxPktSize then no additional zero-byte packet is sent when using Generic RNDIS transfer. Generic RNDIS transfer makes use of a USB0/1 GENERIC RNDIS EPn Size register (there exists a register for each endpoint) that must be programmed with the transfer size (in bytes) of the transfer for the USB Module (USB0 or USB1) prior to posting a transfer transaction. If the transfer size is an integer multiple of USB MaxPktSize then no additional zero-byte packet is sent when using Generic RNDIS transfer. However, if the a short packet has been sent prior to programmed size count, the transfer would end in a similar fashion an RDIS transfer would behave. For example, it the USB MaxPktSize (Tx/RxMaxP) is programmed with a value of 64, the Generic RNDIS EP Size register for that endpoint must be programmed with a value that is an integer multiple of 64 (for example, 64, 128, 192, 256, etc.) for it behave differently than RNDIS transfer. In other words, when using Generic RNDIS mode and the DMA is tasked to transfer data transfer size that is less or equal the size value programmed within the USB0/1 GENERIC RNDIS EPn Size register.

This means that Generic RNDIS mode will perform data transfer in the same manner as RNDIS mode, closing the CPPI packet if a USB packet with a size less than the USB MaxPktSize size value is received. Otherwise, the packet will be closed when the value in the Generic RNDIS EP Size register is reached.

Using USB0/1 GENERIC RNDIS EPn Size register, a packet of up to 64K bytes (65536 bytes) can be transferred. This is to allow the host software to program the USB module to transfer data that is an exact multiple of the USB MaxPktSize (Tx/RxMaxP programmed value) without having to send an additional short packet to terminate.

NOTE: As in RNDIS mode, the USB max packet size (Tx/RxMaxp programmed value) of any Generic RNDIS mode enabled endpoints must be a multiple of 64 bytes. Generic RNDIS acceleration should not be enabled for endpoints where the max packet size is not a multiple of 64 bytes. Only transparent mode should be used for such endpoints.

15.3.9.8.3.1 Generic RNDIS DMA Transfer Setup

Disable the use of RNDIS at the global level, this is achieved by clearing RNDIS bit field (CTRLR0/1[RNDIS]=0), since global configuration over-rides endpoint configuration.

Configure the field that correspond to the USB module endpoint using the corresponding USB0/1 TX(RX) Mode Register, i.e., TXMODE0/1[TXn_MODE] = 11b and RXMODE0/1[RXn_MODE] = 11b.

15.3.9.8.4 Linux CDC DMA Transfer

Linux CDC DMA transfer mode acts in the same manner as RNDIS packets, except for the case where the last data matches the max USB packet size requiring additional zero-byte packet transfer in RNDIS mode and this is not the case for Linux CDC. If the last data packet of a transfer is a short packet where the data size is greater than zero and less the USB MaxPktSize, then the behavior of the Linux CDC DMA transfer type is identical with the RNDIS DMA transfer type. The only exception is when the short packet length terminating the transfer is a Null Packet. In this case, instead of transferring the Null Packet, it will transfer a data packet of size 1 byte with the data value of 00h.

In transmit operation, if an endpoint is configured or CDC Linux mode, upon receiving a Null Packet from the CPPI DMA, the XFER DMA will then generate a packet containing 1 byte of data, whose value is 00h, indicating the end of the transfer. During receive operation, the XFER DMA will recognize the one byte zero packet as a termination of the data transfer, and sends a block of data with the EOP indicator set and a byte count of one to the CPPI DMA controller. The CPPI DMA realizing the end of the transfer termination will not update/increase the packet size count of the Host Packet Descriptor.

Copyright © 2011, Texas Instruments Incorporated

15.3.9.8.4.1 Linux CDC DMA Transfer Setup

Disable the use of RNDIS at the global level, this is achieved by clearing RNDIS bit field (CTRLR0/1[RNDIS]=0), since global configuration over-rides endpoint configuration.

Configure the field that correspond to the USB module endpoint using the corresponding USB0/1 TX(RX) Mode Register, i.e., TXMODE0/1[TXn_MODE] = 10b and RXMODE0/1[RXn_MODE] = 10b.

15.3.9.9 USB Data Flow Using DMA

The necessary steps required to perform a USB data transfer using the CPPI 4.1 DMA is expressed using an example for both transmit and receive cases. Assume USB0 is ready to perform a USB data transfer of size 608 bytes (see Figure 15-17).

The 608 bytes data to be transferred is described using three descriptors. Since each data buffer defined within a single descriptor has a size of 256 bytes, a 608 bytes data buffer would require three descriptors.

Figure 15-17. High-level Transmit and Receive Data Transfer Example

Example assumptions:

- The CPPI data buffers are 256 bytes in length.
- USB0 module is to be used to perform this transfer. Note that the steps required is similar for USB1 use.
- The USB0 endpoint 1 Tx and Rx endpoint 1 size are programmed to handle max USB packet size of 512 bytes.
- A single transfer length is 608 bytes.
- The SOP offset is 0.

The above translates to the following multi-descriptor setup:

Transmit Case

Transmit setup is as follows:

- One packet descriptor with packet length (this is NOT data buffer length, the term packet used here is to mean a transfer length not USB packet) field of 608 bytes and a Data Buffer of size 256 Bytes linked to the 1st host buffer descriptor.
- Two buffer descriptors with first buffer descriptor (this is the one linked to the packet descriptor) defining the second data buffer size of 256 Bytes which in turn is linked to the next (second) buffer descriptor.

Copyright © 2011, Texas Instruments Incorporated

- Second buffer fescriptor with a fata buffer size of 96 bytes (can be greater, the packet descriptor contain the size of the packet) linked to no other descriptor (NULL).

Receive Case

For this example since each data buffer size is 256 bytes, we would require a minimum of three descriptors that would define data buffer size of 608 bytes. The receive setup is as follows:

- Two buffer descriptors with 256 bytes of data buffer size
- One buffer descriptor with 96 bytes (can be greater) of data buffer size

Within the rest of this section, the following nomenclature is used:

BD — Buffer Descriptor or Host Buffer Descriptor

DB — Data Buffer Size of 256 Bytes

PBD — Pointer to Host Buffer Descriptor

PD — Host Packet Descriptor

PPD — Pointer to Host Packet Descriptor

TXSQ — Transmit Queue or Transmit Submit Queue (for USB0 EP1, use Queues 32 or 33, for USB1 EP1 use Queues 62 or 63)

TXCQ — Transmit Completion Queue or Transmit Return Queue (for USB0 Tx EP1, use Queue 93, and for USB1 Tx EP1 use Queue 125)

RXCQ — Receive Completion Queue or Receive Return Queue (for USB0 Rx EP1, use Queue 109, for USB1 Rx EP1 use Queue 141)

RXSQ — Receive Free/Buffer Descriptor Queue or Receive Submit Queue. (For USB0 Rx EP1 Queue 0 is used and for USB1 Rx EP1 Queue 16 should be used

15.3.9.9.1 Transmit USB Data Flow Using DMA

The transmit descriptors and queue status configuration prior to the transfer taking place is shown in Figure 15-18.

Figure 15-18. Transmit Descriptors and Queue Status Configuration

15.3.9.9.1.1 Transmit Initialization (Step 1)

The CPU performs the following steps for transmit initialization:

1. Initializes Memory Region 0 base address and Memory Region 0 size, Link RAM0 Base address, Link RAM0 data size, and Link RAM1 Base address.
2. Creates PD, BDs, and DBs in main memory and link as indicated in Figure 15-19.
3. Initializes and configures the Queue Manager, Channel Setup, DMA Scheduler, and Mentor USB 2.0 Core.
4. Adds (pushes) the PPD and the two PBDs to the TXSQ by writing the Packet Descriptor address to the TXSQ CTRL D Register.

Figure 15-19 captures the BD/DB pair in main memory and later submitted within the TXSQ.

Copyright © 2011, Texas Instruments Incorporated

Figure 15-19. Transmit USB Data Flow Example (Initialization)

15.3.9.9.1.2 CDMA and XDMA Transfer Packet Data Into Endpoint FIFO (Step 2)

The steps for CDMA and XDMA to transfer packet data into endpoint FIFO are as follows:

1. The Queue Manager informs the CDMAS that the TXSQ is not empty.
2. CDMAS checks that the CPPI FIFO FIFO_full is not asserted, then issues a credit to the CDMA.
3. CDMA reads the Packet Descriptor pointer (PPD) and descriptor size hint from the queue manager
4. For each 64-byte block of data in the packet data payload (note that packet refers here to CPPI packet which is not the same as USB packet and it means to refer to data transfer size):
   (a) The CDMA transfers a max burst of 64-byte block (OCP burst) from the data to be transferred in main memory to the CPPI FIFO
   (b) The XDMA sees FIFO_empty not asserted and transfers 64-byte block from CPPI FIFO to Endpoint FIFO.
   (c) The CDMA performs the above two steps (‘a’ and ‘b’) three more times since the data size of the HPD is 256 bytes.
5. The CDMA reads the first buffer descriptor pointer (PBD).
6. For each 64-byte block of data in the packet data payload:
   (a) The CDMA transfers a max burst of 64-byte block from the data to be transferred in main memory to the CPPI FIFO.
   (b) The XDMA sees FIFO_empty not asserted and transfers 64-byte block from CPPI FIFO to Endpoint FIFO.
   (c) The CDMA performs the above two steps (‘a’ and ‘b’) two more times since data size of the HBD is 256 bytes.
7. The CDMA reads the second Buffer Descriptor pointer (PBD
8. For each 64-byte block of data in the packet data payload:
   (a) The CDMA transfers a max burst of 64-byte block from the data to be transferred in main memory to the CPPI FIFO.
   (b) The XDMA sees FIFO_empty not asserted and transfers 64-byte block from CPPI FIFO to Endpoint FIFO.
   (c) The CDMA transfers the last remaining 32-byte from the data to be transferred in main memory to the CPPI FIFO.
   (d) The XDMA sees FIFO_empty not asserted and transfers 32-byte block from CPPI FIFO to Endpoint FIFO.

Copyright © 2011, Texas Instruments Incorporated

15.3.9.9.1.3 USB 2.0 Core Transmits USB Packets for Tx (Step 3)

1. Once the XDMA has transferred enough 64-byte blocks of burst of data from the CPPI FIFO to fill the Endpoint FIFO (accumulated 512 bytes), it signals the Mentor USB 2.0 Core that a TX packet is ready (sets the endpoint's TxPktRdy bit).
2. The USB 2.0 Core will transmit the packet from the Endpoint FIFO out on the USB BUS when it receives a corresponding IN request from the attached USB Host.
3. After the USB packet is transferred, the USB 2.0 Core issues a TX DMA_req to the XDMA.
4. This process is repeated until (the above steps '1', '2', and '3') the entire packet has been transmitted. The XDMA will also generate the required termination packet depending on the termination mode configured for the endpoint.

15.3.9.9.1.4 Return Packet to Completion Queue and Interrupt CPU for Tx (Step 4)

1. After all data for the packet has been transmitted (as specified by the packet size field), the CDMA will write the pointer of the Packet Descriptor only to the TX Completion Queue specified in the return queue manager / queue number fields of the packet descriptor.
2. The Queue Manager then indicates the status of the TXSQ (empty) to the CDMAS and the TXCQ to the CPU via an interrupt.

15.3.9.9.2 Receive USB Data Flow Using DMA

The receive buffer descriptors and queue status configuration prior to the transfer taking place is shown in Figure 15-20.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Figure 15-20. Receive Buffer Descriptors and Queue Status Configuration

15.3.9.9.2.1 Receive Initialization (Step 1)

1. The CPU initializes Queue Manager with the Memory Region 0 base address and Memory Region 0 size, Link RAM0 Base address, Link RAM0 data size, and Link RAM1 Base address.
2. The CPU creates BDs, and DBs in main memory and link them creating a BD and DB pairs.
3. CPU then initializes the RXCQ queue and configures the Queue Manager, Channel Setup, DMA Scheduler, and USB 2.0 Core.
4. It then adds (pushes) the address of the addresses/pointers of three Buffer Descriptors (PBDs) into the

Copyright © 2011, Texas Instruments Incorporated

RXSQ by writing onto CTRL D register.

Figure 15-21 displays receive operation Initialization.

Figure 15-21. Receive USB Data Flow Example (Initialization)

15.3.9.9.2.2 USB 2.0 Core Receives a Packet, XDMA Starts Data Transfer for Receive (Step 2)

1. The USB 2.0 Core receives a USB packet from the USB Host and stores it in the Endpoint FIFO.
2. It then asserts a DMA_req to the XDMA informing it that data is available in the Endpoint FIFO.
3. The XDMA verifies the corresponding CPPI FIFO is not full via the FIFO_full signal, then starts transferring 64-byte data blocks (burst) from the Endpoint FIFO into the CPPI FIFO.

15.3.9.9.2.3 CDMA Transfers Data from SSRAM / PPU to Main Memory for Receive (Step 3)

1. The CDMAS see FIFO_empty de-asserted (there is RX data in the FIFO) and issues a transaction credit to the CDMA.
2. The CDMA begins packet reception by fetching the first PBD from the Queue Manager using the Free Descriptor / Buffer Queue 0 (Rx Submit Queue) index that was initialized in the RX port DMA state for that channel.
3. The CDMA will then begin writing the 64-byte block of packet data into this DB.
4. The CDMA will continue filling the buffer with additional 64-byte blocks of data from the CPPI FIFO and will fetch additional PBD as needed using the Free Descriptor / Buffer Queue 1, 2, and 3 indexes for the 2nd, 3rd, and remaining buffers in the packet. After each buffer is filled, the CDMA writes the buffer descriptor to main memory.

15.3.9.9.2.4 CDMA Completes the Packet Transfer for Receive (Step 4)

1. After the entire packet has been received, the CDMA writes the packet descriptor to main memory.
2. The CDMA then writes the packet descriptor to the RXCQ specified in the Queue Manager / Queue Number fields in the RX Global Configuration Register.
3. The Queue Manager then indicates the status of the RXCQ to the CPU via an interrupt.
4. The CPU can then process the received packet by popping the received packet information from the RXCQ and accessing the packet's data from main memory.

15.3.10 USB 2.0 Test Modes

The USB2.0 controller supports the four USB 2.0 test modes (Test_SE0_NAK, Test_J, Test_K, and Test_Packet) defined for high-speed functions. It also supports an additional “FIFO access” test mode that can be used to test the operation of the CPU interface, the DMA controller and the RAM block.

The test modes are entered by writing to the TESTMODE register. A test mode is usually requested by the host sending a SET_FEATURE request to Endpoint 0. When the software receives the request, it should wait until the Endpoint 0 transfer has completed (when it receives the Endpoint 0 interrupt indicating the status phase has completed) then write to the TESTMODE register.

Note: These test modes have no purpose in normal operation.

15.3.10.1 TEST_SE0_NAK

To enter the Test_SE0_NAK test mode, the software should set the TEST_SE0_NAK bit in the TESTMODE register to 1. The USB controller will then go into a mode in which it responds to any valid IN token with a NAK.

15.3.10.2 TEST_J

To enter the Test_J test mode, the software should set the TEST_J bit in the TESTMODE register to 1. The USB controller will then go into a mode in which it transmits a continuous J on the bus.

15.3.10.3 TEST_K

To enter the Test_K test mode, the software should set the TEST_K bit in the TESTMODE register to 1. The USB controller will then go into a mode in which it transmits a continuous K on the bus.

15.3.10.4 TEST_PACKET

To execute the Test_Packet, the software should:

1. Start a session (if the core is being used in Host mode.
2. Write the standard test packet (shown below) to the Endpoint 0 FIFO.
3. Write 8h to the TESTMODE register (TEST_PACKET = 1) to enter Test_Packet test mode.
4. Set the TxPktRdy bit in the HOST/PERI_CSR0 register (bit 1).

The 53 byte test packet to load is as follows (all bytes in hex). The test packet only has to be loaded once; the USB controller will keep re-sending the test packet without any further intervention from the software.

Table 15-28 displays the 53 Bytes test packet content.

Table 15-28. 53 Bytes Test Packet Content

0	0	0	0	0	0	0	0
0	AA	AA	AA	AA	AA	AA	AA
AA	EE	EE	EE	EE	EE	EE	EE
EE	FE	FF	FF	FF	FF	FF	FF
FF	FF	FF	FF	FF	7F	BF	DF
EF	F7	FB	FD	FC	7E	BF	DF
EF	F7	FB	FD	7E			

This data sequence is defined in Universal Serial Bus Specification Revision 2.0, Section 7.1.20. The USB controller will add the DATAA0 PID to the head of the data sequence and the CRC to the end.

15.3.10.5 FIFO_ACCESS

The FIFO Access test mode allows you to test the operation of CPU Interface, the DMA controller (if configured), and the RAM block by loading a packet of up to 64 bytes into the Endpoint 0 FIFO and then reading it back out again. Endpoint 0 is used because it is a bidirectional endpoint that uses the same area of RAM for its Tx and Rx FIFOs.

NOTE: The core does not need to be connected to the USB bus to run this test. If it is connected, then no session should be in progress when the test is run.

The test procedure is as follows:

1. Load a packet of up to 64 bytes into the Endpoint 0 Tx FIFO.
2. Set HOST/PERI_CSR0[TXPKTRDY].
3. Write 40h to the TESTMODE register (FIFO_ACCESS = 1).
4. Unload the packet from the Endpoint Rx FIFO, again.
5. Set HOST/PERI_CSR0[SERVICEDRXPKTRDY].

Writing 40h to the TESTMODE register causes the following sequence of events:

The Endpoint 0 CPU pointer (that records the number of bytes to be transmitted) is copied to the Endpoint 0 USB pointer (that records the number of bytes received).

1. The Endpoint 0 CPU pointer is reset.
2. HOST/PERI_CSR0[TXPKTRDY] is cleared.
3. HOST/PERI_CSR0[RXPKTRDY] is set.
4. An Endpoint 0 interrupt is generated (if enabled).

The effect of these steps is to make the Endpoint 0 controller act as if the packet loaded into the Tx FIFO has flushed and the same packet received over the USB. The data that was loaded in the Tx FIFO can now be read out of the Rx FIFO.

15.3.10.6 FORCE_HOST

The Force Host test mode enables you to instruct the core to operate in Host mode, regardless of whether it is actually connected to any peripheral; that is, the state of the CID input and the LINESTATE and HOSTDISCON signals are ignored. (While in this mode, the state of the HOSTDISCON signal can be read from the BDEVICE bit in the device control register (DEVCTL)) .

This mode, which is selected by writing 80h to the TESTMODE register (FORCE_HOST = 1), allows implementation of the USB Test_Force_Enable (USB 2.0 Specification Section 7.1.20). It can also be used for debugging PHY problems in hardware.

While the FORCE_HOST bit remains set, the core enters the Host mode when the SESSION bit in DEVCTL is set to 1 and remains in the Host mode until the SESSION bit is cleared to 0 even if a connected device is disconnected during the session. The operating speed while in this mode is determined by the FORCE_HS and FORCE_FS bits in the TESTMODE register.

15.4 Supported Use Cases

The USB Subsystem supports two independent USB Modules where each USB module can operate as a host or peripheral. When operating as a host, it is capable of interfacing to a single target/peripheral directly or to multiple targets via hub at low-, full-, or high-speed. When operating as a peripheral, it is capable of interfacing to a host at a full- or high-speed.

15.5.1.2 USBSS SYSCONFIG Register (SYSCONFIG)

The SYSCONFIG register is the clock management configuration register for the USBSS.

The clock enable bits 8 to 11 should only be configured/modified during the firmware initialization stage of the USBSS. In other words, these bits should not be modified while the system is running or after enabling the clock. These bits control the clock generation modules. Dynamically setting these bits can disable the power management logic. The USBSS SYSCONFIG register is shown in shown in Figure 15-23 and described in Table 15-31.

15.5.1.3 USBSS End of Interrupt Register (EOI)

The USBSS end of interrupt register (EOI) allows the CPU to acknowledge completion of an interrupt by writing 0, zero, to the EOI_VECTOR field. An eoi_write signal will be generated and another interrupt will be triggered if interrupt sources remain.

This register will be reset one cycle after it has been written to. The USBSS end of interrupt register is shown in Figure 15-24 and described in Table 15-32.

15.5.1.4 USBSS IRQ_STATUS_RAW (IRQSTATRAW)

The USBSS IRQSTATRAW register allows the USBSS interrupt sources to be manually triggered when writing a 1 to a specific bit. A read from this register returns the USBSS interrupt event pending value. This register is shown in Figure 15-25 and described in Table 15-33.

General actions per bit:
Write 0: No action
Write 1: Set event
Read 0: No event pending
Read 1: Event pending

15.5.1.5 USBSS IRQ_STATUS Register (IRQSTAT)

The USBSS IRQSTAT register contains the interrupt sources status of the enabled interrupt. IRQSTAT register is a subset of IRQSTATRAW register. Writing a '1' to a bit field will clear a pending interrupt event. This register is shown in Figure 15-26 and described in Table 15-34.

General actions per bit:
Write 0: No action
Write 1: Clear event
Read 0: No event pending
Read 1: Event pending

15.5.1.6 USBSS IRQ_ENABLE_SET Register (IRQENABLER)

The USB interrupt mask set register (IRQENABLER) allows the USB interrupts to be enabled (unmasked). A read from this register returns the USB interrupts enabled.

The USBSS IRQ_ENABLE_SET register is shown in Figure 15-27 and described in Table 15-35.

General actions per bit:
Write 0: No action
Write 1: Interrupt enabled
Read 0: Interrupt disabled
Read 1: Interrupt enabled

15.5.1.7 USBSS IRQ_ENABLE_CLR Register (IRQCLEARR)

The USBSS IRQCLEARR register allows the USBSS interrupt sources to be masked when writing a 1 to a specific bit. A read of this register returns the USBSS interrupt enabled value.

The USBSS IRQ_ENABLE_CLR register is shown in Figure 15-28 and described in Table 15-36.

General actions per bit:
Write 0: No action
Write 1: Disable interrupt
Read 0: Interrupt disabled
Read 1: Interrupt enabled

15.5.1.8 USBSS IRQ_DMA_THRESHOLD_TX0_0 Register (IRQDMATHOLDTX00)

The USBSS IRQDMATHOLDTX00 register defines the size of the four DMA thresholds for interrupt pacing for USB0. Each threshold contains an 8-bit unsigned number and can range from 0 to 255. A possible interrupt can be triggered if the count for that specific endpoint has exceeded the value of the threshold. The counter for the compared value is also an 8-bit unsigned number; therefore, setting the threshold to 255 prevents the possibility of a trigger.

The USBSS IRQ_DMA_THRESHOLD_TX0_0 register is shown in Figure 15-29 and described in Table 15-37.

Figure 15-29. USBSS IRQ_DMA_THRESHOLD_TX0_0 Register (IRQDMATHOLDTX00)

15-8	dma_thres_tx1_9	DMA threshold value for tx_pkt_cmp_0 for USB1 Endpoint 9
7-0	dma_thres_tx1_8	DMA threshold value for tx_pkt_cmp_0 for USB1 Endpoint 8

15.5.1.19 USBSS IRQ_DMA_THRESHOLD_TX1_3 Register (IRQDMATHOLDTX13)

The USBSS IRQDMATHOLDTX13 register defines the size of the four DMA thresholds for interrupt pacing for USB1. Each threshold contains an 8-bit unsigned number and can range from 0 to 255. A possible interrupt can be triggered if the count for that specific endpoint has exceeded the value of the threshold. The counter for the compared value is also an 8-bit unsigned number; therefore, setting the threshold to 255 prevents the possibility of a trigger.

The USBSS IRQ_DMA_THRESHOLD_TX1_3 register is shown in Figure 15-40 and described in Table 15-48.

15.5.1.24 USBSS IRQ_DMA_ENABLE_0 Register (IRQDMAENABLE0)

The USBSS IRQDMAENABLE0 contains 32 enables. Sixteen enables are assigned to the 16 endpoints associated with the tx_pkt_cmp_0 interrupt and 16 enables are assigned to the 16 endpoints associated with the rx_pkt_cmp_0 interrupt. Endpoint 0 for both the tx and rx does not exist; but it is included for completeness of this register.

If the enable is set; then that specific endpoint can generate an interrupt if the event pending count has exceeded the threshold.

If the enable is cleared; then that specific endpoint cannot generate an interrupt regardless if the event pending count has exceeded the threshold or not.

The USBSS IRQ_DMA_ENABLE_0 Register is shown in Figure 15-45 and described in Table 15-53.

15.5.1.26 USBSS IRQ_FRAME_THRESHOLD_TX0_0 Register (IRQFRAMETHOLD00)

The USBSS IRQFRAMETHOLDTX00 register defines the size of the four FRAME thresholds for interrupt pacing for USB0. Each threshold contains is an 8-bit unsigned number and can range from 0 to 255. A possible interrupt can be triggered if the count for that specific endpoint has exceeded the value of the threshold. The counter for the compared value is also an 8-bit unsigned number; therefore, setting the threshold to 255 prevents the possibility of a trigger.

The USBSS IRQ_FRAME_THRESHOLD_TX0_0 register is shown in Figure 15-47 and described in Table 15-55.

Figure 15-47. USBSS IRQ_FRAME_THRESHOLD_TX0_0 Register (IRQFRAMETHOLD00)

15.5.1.29 USBSS IRQ_FRAME_THRESHOLD_TX0_3 Register (IRQFRAMETHOLDTX03)

The USBSS IRQFRAMETHOLDTX03 register defines the size of the four FRAME thresholds for interrupt pacing for USB0. Each threshold contains is an 8-bit unsigned number and can range from 0 to 255. A possible interrupt can be triggered if the count for that specific endpoint has exceeded the value of the threshold. The counter for the compared value is also an 8-bit unsigned number; therefore, setting the threshold to 255 prevents the possibility of a trigger.

The USBSS IRQ_FRAME_THRESHOLD_TX0_3 register is shown in Figure 15-50 and described in Table 15-58.

15.5.1.42 USBSS IRQ_FRAME_ENABLE_0 Register (IRQFRAMEENABLE0)

The USBSS IRQFRAMEENABLE0 register contains 32 enables for USB0. Sixteen enables are assigned to the 16 endpoints associated with the tx_pkt_cmp_0 interrupt and 16 enables are assigned to the 16 endpoints associated with the rx_pkt_cmp_0 interrupt. Endpoint 0 for both the tx and rx does not exist; but it is included for completeness of this register.

If the enable is set; then that specific endpoint can generate an interrupt if the frame count has exceeded the threshold. If the enable is not set; then no hardware interrupt will be generated for that specific endpoint. It is still possible to generate the interrupt via software.

If the enable is cleared; then that specific endpoint cannot generate an interrupt regardless if the frame count has exceeded the threshold or not.

The USBSS IRQ_FRAME_ENABLE_0 register is shown in Figure 15-63 and described in Table 15-71.

15.5.1.43 USBSS IRQ_FRAME_ENABLE_1 Register (IRQFRAMEENABLE1)

The USBSS IRQFRAMEENABLE1 register contains 30 enables for USB1. Fifteen enables are assigned to the 15 endpoints associated with the tx_pkt_cmp_1 interrupt and 15 enables are assigned to the 15 endpoints associated with the rx_pkt_cmp_1 interrupt. Endpoint 0 for both the tx and rx does not exist; but it is included for completeness of this register.

If the enable is set; then that specific endpoint can generate an interrupt if the frame count has exceeded the threshold. If the enable is not set; then no hardware interrupt will be generated for that specific endpoint. It is still possible to generate the interrupt via software.

If the enable is cleared; then that specific endpoint cannot generate an interrupt regardless if the frame count has exceeded the threshold or not. The USBSS IRQ_FRAME_ENABLE_1 register is shown in Figure 15-64 and described in Table 15-72.

15.5.2.1.2 USB0 Control Register (USB0CTRL)

The USB0 control register (USB0CTRL) allows the CPU to control various aspects of the module. If uint is set high, then the Mentor controller generic interrupt for USB[9] will be generated (if enabled). This requires software to read the Mentor controller's registers to determine which interrupt USB[0] to USB[7] occurred. If uint is set low, then the usb20otg_f module will automatically read the Mentor controller's registers and set the appropriate interrupt USB[0] to USB[7] (if enabled). The generic interrupt for USB[9] will not be generated.

The USB0 control register is shown in Figure 15-66 and described in Table 15-75.

Figure 15-66. USB0 Control Register (USB0CTRL)

31	30	29 … 16
dis_deb	dis_srp	Reserved
R/W-0h	R/W-0h	R-0h

15 … 8
Reserved
R-0h

7 … 6	5	4	3	2	1	0
Reserved	soft reset isolation	rndis	uint	Reserved	clkfack	soft reset
R-0h	R/W-0h	R/W-0h	R/W-0h	R-0h	R/W-0h	R/W1-0

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 15-75. USB0 Control Register (USB0CTRL) Field Descriptions

Bits	Field	Value	Description
31	dis_deb		Disable the VBUS debouncer circuit fix
30	dis_srp		Disable the OTG Session Request Protocol (SRP) AVALID circuit fix. When enabled (=0) this allows additional time for the VBUS signal to be measured against the VBUS thresholds. The time is specified in the USB0 SRP Fix Time Register.
29-6	Reserved		Always read as 0. Writes have no effect.
5	soft reset isolation		Soft reset isolation. When high this bit forces all USB0 signals that connect to the USBSS to zeros during a soft reset via bit 0 of this register. This bit should be set high prior to setting bit 0 and cleared after bit 0 is cleared.
4	rndis		Global RNDIS mode enable for all endpoints
3	uint		USB non-Highlander interrupt enable
		1	Non-Highlander
		0	Highlander
2	Reserved		Always read as 0. Writes have no effect.
1	clkfack		Clock stop fast ack enable
0	soft reset		Software reset of USB0
		Write 0	No action
		Write 1	Initiate software reset
		Read 0	Reset done, no action
		Read 1	Reset ongoing

15.5.2.1.3 USB0 Status Register (USB0STAT)

The USB0 status register (USB0STAT) allows the CPU to check the voltage state level of USB0_DRVVBUS pin. The USB0 status register is shown in Figure 15-67 and described in Table 15-76.

Figure 15-67. USB0 Status Register (USB0STAT)

31	1	0
Reserved		drvvbus
R-0h		R-0h

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Bits	Field	Description
31-1	Reserved	Always read as 0. Writes have no effect.
0	drvvbus	Current USB0_DRVVBUS value

15.5.2.1.4 USB0 IRQ_MERGED_STATUS Register (USB0IRQMSTAT)

The USB0 IRQ_MERGED_STATUS register (USB0IRQMSTAT) register contains a merged status for all the events for USB0. This register optimizes software accesses in a module where a large number of events are associated to one IRQ line. The merged status is read-only, and does not need to be actively cleared like the IRQ status. It will clear automatically.

The USB0 IRQ_MERGED_STATUS register is shown in Figure 15-68 and described in Table 15-77.

Figure 15-68. USB0 IRQ_MERGED_STATUS Register (USB0IRQMSTAT)

15.5.2.1.5 USB0 IRQ_EOI Register (USB0IRQEOI)

The USB0 IRQ_EOI register (USB0IRQEOI) allows the CPU to acknowledge completion of an interrupt by writing to the EOI. An eoi_write signal will be generated and another interrupt will be triggered if interrupt sources remain.

This register will be reset one cycle after it has been written to.

The USB0 IRQ_EOI register is shown in Figure 15-69 and described in Table 15-78.

Figure 15-69. USB0 IRQ_EOI Register (USB0IRQEOI)

31	1	0

15.5.2.1.6 USB0 IRQ_STATUS_RAW_0 Register (USB0IRQSTATRAW0)

The USB0 IRQ_STATUS_RAW_0 register (USB0IRQSTATRAW0) allows the USB0 interrupt sources to be manually triggered when writing a 1 to a specific bit. A read of this register returns the USB0 interrupt event pending value.

General actions per bit:
Write 0: No action
Write 1: Set event
Read 0: No event pending
Read 1: Event pending

The USB0 IRQ_STATUS_RAW_0 register is shown in Figure 15-70 and described in Table 15-79.

15.5.2.1.8 USB0 IRQ_STATUS_0 Register (USB0IRQSTAT0)

The USB0 IRQ_STATUS_0 register (USB0IRQSTAT0) allows the USB0 interrupt sources to be manually cleared when writing a 1 to a specific bit. A read of this register returns the USB0 interrupt event pending value.

General actions per bit:
Write 0: No action
Write 1: Clear event
Read 0: No event pending
Read 1: Event pending

The USB0 IRQ_STATUS_0 register is shown in Figure 15-72 and described in Table 15-81.

15.5.2.1.16 USB0 Generic RNDIS EPn Size Register (USB0GENRNDISEPn)

The USB0 generic RNDIS EPn size register (USB0GENRNDISEPn) is programmed with a RNDIS packet size in bytes. When EP(n) is in Generic RNDIS mode, the received USB packets will be collected into a single CPPI packet that is completed when the number of bytes equal to the value of this register has been received, or a “short” packet is received. Note that this register must be programmed with a value that is an integer multiple of the endpoint size. The maximum value this register can be programmed with is 0x10000, or 65536. N can range from 1 to 15.

The USB0 generic RNDIS EPn size register is shown in Figure 15-80 and described in Table 15-89.

15.5.2.1.17 USB0 Auto Req Register (USB0AUTOREQ)

The USB0 auto req register (USB0AUTOREQ) allows the CPU to enable an automatic IN token request generation for host mode RX operation per each RX endpoint. This feature has the DMA set the ReqPkt bit in the RXCSR when it clears the RxPktRdy bit after reading out a packet. The ReqPkt bit is used by the core to generate an IN token to receive data. By using this feature, the host can automatically generate an IN token after the DMA finishes receiving data and empties an endpoint buffer, thus receiving the next data packet as soon as possible from the connected device. Without this feature, the CPU will have to manually set the ReqPkt bit for every USB packet.

There are two modes that Auto Req can function: always or all except an EOP. The always mode will set the ReqPkt bit after every USB packet the DMA receives thus generating a new IN token after each USB packet. The EOP mode will set the ReqPkt bit after every USB packet that isn't an EOP (end of packet) in the CPPI descriptor. For RNDIS, CDC, and Generic RNDIS modes the auto req will stop when the EOP is received (either via a short packet for RNDIS,CDC, and Generic RNDIS or the count is reached for Generic RNDIS), making it useful for starting a large RNDIS packet and having it auto generate IN tokens until the end of the RNDIS packet. For transparent mode every USB packet is an EOP CPPI packet so the auto req never functions and acts like auto req is disabled.

The USB0 auto req register is shown in Figure 15-81 and described in Table 15-90.

Figure 15-81. USB0 Auto Req Register (USB0AUTOREQ)

15.5.2.1.18 USB0 SRP Fix Time Register (USB0SRPFIXTIME)

The USB0 SRP fix time register (USB0SRPFIXTIME) allows the CPU to configure the maximum amount of time the SRP fix logic blocks the AVAID from the PHY to the OTG core. This time allows the VBUS signal the ability to get below the thresholds and therefore remove the chance of voltage bounces which could give false threshold measurements.

The USB0 SRP fix time register is shown in Figure 15-82 and described in Table 15-91.

Figure 15-82. USB0 SRP Fix Time Register (USB0SRPFIXTIME)

Bits	Field	Description
31-0	srpfixtime	SRP Fix maximum time in 60 MHz cycles. Default is 700 ms.

15.5.2.1.19 USB0 Teardown Register (USB0TDOWN)

The USB0 teardown register (USB0TDOWN) controls the tearing down of rx and tx fifos in the USB controller. When a '1' is written to a valid bit in this register, the CPPI FIFO pointers for that endpoint are cleared, and the register automatically clears itself after 1 clock cycle. This register must be used in conjunction with the CPPI DMA Teardown mechanism. The host should also write the FlushFIFO bits in the TXCSR and RXCSR Mentor USB Controller registers to ensure a complete teardown of the endpoint. See the Mentor specification for details.

The USB0 teardown register is shown in Figure 15-83 and described in Table 15-92.

15.5.2.1.20 USB0 PHY UTMI Register (USB0UTMI)

The USB0 PHY UTMI register (USB0UTMI) controls various PHY UTMI signals. The UTMI interface is located between the PHY module and the Mentor Graphics Controller. These signals are inputs to the PHY but are not outputs from the Mentor Graphics Controller.

It is important to set the otgdisable bit in to a high value to operate the PHY in a non-OTG mode. The USB0 PHY UTMI register is shown in Figure 15-84 and described in Table 15-93.

15.5.2.1.21 USB0 MGC UTMI Loopback Register (USB0UTMILB)

The USB0 MGC UTMI loopback register (USB0UTMILB) contains most of the input and output UTMI signals for the Mentor Graphics Controller. The UTMI interface is located between the PHY module and the Mentor Graphics Controller.

In the loopback mode test register bits 11 to 0 control various UTMI signals that are input to the Mentor Graphics Controller.

In the loopback mode test register bits 28 to 16 observe various UTMI signals that are output from the Mentor Graphics Controller.

The USB0 MGC UTMI loopback register is shown in Figure 15-85 and described in Table 15-94.

15.5.2.1.22 USB0 Mode Register (USB0MODE)

The USB mode (USB0MODE) register allows the user a flexibility of controlling the role that the controller assumes. Via the setting of the USB0MODE[Bit7=Iddig_Mux], the user has the capability of allowing the control to be coming from a register field (USB0MODE[Bit8=iddig]) or from the USB_ID pin which is indirectly controlled by the cable end. if USB0MODE[iddig_mux]=0, the state of the USB_ID pin controls the role the controller assumes. However, if USBMODE[Iddig_mux]=1, then the setting USB0MODE[iddig] will control the role the controller assumes.

The loopback bit enables the loopback test. This test allows MGC0 to be connected to MGC1. It is important to set both loopback bits in both USB0/1 Mode registers. The USB0 MGC UTMI loopback register contains the various UTMI signals to be controlled and observed during loopback test.

The phy_test bit enables the phy_test mode. This test mode is intended to allow additional control of the UTMI inputs to the PHY. Currently, these inputs are drvvbus, dppulldown, dmpulldown, and idpullup. When phy_test is high, then the pin inputs for these signals control the inputs to the PHY instead of the Mentor controller outputs. The phy_test mode is not active with loopback mode is active.

When phy_test is active than the PHY inputs datainh is equal to datain. And txvalidh is equal to txvalid.

The USB0 mode register is shown in Figure 15-86 and described in Table 15-95.

15.5.2.1.23 USB0 Mentor Core Registers

A description of the Mentor core registers is available in Section 15.5.6. Two instantiations of the USB core exists, USB0 and USB1. These registers reside back to back within USB0 space. The core registers that are used by USB0 subsystem are defined within offsets 1400h-159Ch, while the core registers that are used by USB1 subsystem are defined within offset 1C00h-1D9Ch.

15.5.2.2.2 USB1 Control Register (USB1CTRL)

The USB1 control register (USB1CTRL) allows the CPU to control various aspects of the module. If uint is set high, then the Mentor controller generic interrupt for USB[9] will be generated (if enabled). This requires software to read the Mentor controller's registers to determine which interrupt USB[0] to USB[7] occurred. If uint is set low, then the usb20otg_f module will automatically read the Mentor controller's registers and set the appropriate interrupt USB[0] to USB[7] (if enabled). The generic interrupt for USB[9] will not be generated.

The USB1 control register is shown in Figure 15-88 and described in Table 15-98.

Figure 15-88. USB1 Control Register (USB1CTRL)

31	30	29 … 16
dis_deb	dis_srp	Reserved
R/W-0h	R/W-0h	R-0h

15 … 8
Reserved
R-0h

7 … 6	5	4	3	2	1	0
Reserved	soft reset isolation	rndis	uint	Reserved	clkfack	soft reset
R-0h	R/W-0h	R/W-0h	R/W-0h	R-0h	R/W-0h	R/W1-0

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 15-98. USB1 Control Register (USB1CTRL) Field Descriptions

Bits	Field	Value	Description
31	dis_deb		Disable the VBUS debouncer circuit fix
30	dis_srp		Disable the OTG Session Request Protocol (SRP) AVALID circuit fix. When enabled (=0) this allows additional time for the VBUS signal to be measured against the VBUS thresholds. The time is specified in the USB1 SRP Fix Time Register.
29-06	Reserved	0	Always read as 0. Writes have no effect.
5	soft reset isolation		Soft reset isolation. When high this bit forces all USB1 signals that connect to the USBSS to zeros during a soft reset via bit 0 of this register. This bit should be set high prior to setting bit 0 and cleared after bit 0 is cleared.
4	rndis		Global RNDIS mode enable for all endpoints.
3	uint		USB non-highlander interrupt enable
		0	Highlander
		1	Non-highlander
2	Reserved	0	Always read as 0. Writes have no effect.
1	clkfack		Clock stop fast ack enable.
0	soft reset		Software reset of USB1.
		Write 0	Write 0 = no action
		Write 1	Write 1 = Initiate software reset
			Read 0 = Reset done, no action
			Read 1 = Reset ongoing

If uint is set high, then the Mentor controller generic interrupt for USB[9] will be generated (if enabled). This requires software to read the Mentor controller's registers to determine which interrupt USB[0] to USB[7] occurred.

If uint is set low, then the usb20otg_f module will automatically read the Mentor controller's registers and set the appropriate interrupt USB[0] to USB[7] (if enabled). The generic interrupt for USB[9] will not be generated.

15.5.2.2.3 USB1 Status Register (USB1STAT)

The USB1 status register (USB1STAT) allows the CPU to check the voltage state level of USB1_DRVVBUS pin.

Ths USB1 status register is shown in Figure 15-89 and described in Table 15-99.

Figure 15-89. USB1 Status Register (USB1STAT)

0	drvvbus	Current USB1_DRVVBUS value

15.5.2.2.4 USB1 IRQ_MERGED_STATUS Register (USB1IRQMSTAT)

The USB1 IRQ_MERGED_STATUS register (USB1IRQMSTAT) contains a merged status for all the events for USB1. This register optimizes software accesses in a module where a large number of events are associated to one IRQ line. The merged status is read-only, and does not need to be actively cleared like the IRQ status. It will clear automatically.

The USB1 IRQ_MERGED_STATUS register is shown in Figure 15-90 and described in Table 15-100.

Figure 15-90. USB1 IRQ_MERGED_STATUS Register (USB1IRQMSTAT)

15.5.2.2.5 USB1 IRQ_EOI Register (USB1IRQEOI)

The USB1 IRQ_EOI register (USB1IRQEOI) allows the CPU to acknowledge completion of an interrupt by writing to the end of interrupt (EOI). An eoi_write signal will be generated and another interrupt will be triggered if interrupt sources remain. This register will be reset one cycle after it has been written to.

The USB1 IRQ_EOI register is shown in Figure 15-91 and described in Table 15-101.

Figure 15-91. USB1 IRQ_EOI Register (USB1IRQEOI)

15.5.2.2.6 USB1 IRQ_STATUS_RAW_0 Register (USB1IRQSTATRAW0)

The USB1 IRQ_STATUS_RAW_0 register (USB1IRQSTATRAW0) allows the USB1 interrupt sources to be manually triggered when writing a 1 to a specific bit. A read of this register returns the USB1 interrupt event pending value.

General actions per bit:
Write 0: No action
Write 1: Set event
Read 0: No event pending
Read 1: Event pending

The USB1 IRQ_STATUS_RAW_0 register is shown in Figure 15-92 and described in Table 15-102.

15.5.2.2.15 USB1 Generic RNDIS EP N Size Register (USB1GENRNDISEPn)

The USB1 generic RNDIS EP N size register (USB1GENRNDISEPn) is programmed with a RNDIS packet size in bytes. When EP(N) is in Generic RNDIS mode, the received USB packets will be collected into a single CPPI packet that is completed when the number of bytes equal to the value of this register has been received, or a “short” packet is received. Note that this register must be programmed with a value that is an integer multiple of the endpoint size. The maximum value this register can be programmed with is 10000h, or 65536. N can range from 1 to 15.

The USB1 generic RNDIS EP N size register is shown in Figure 15-101 and described in Table 15-111.

Figure 15-101. USB1 Generic RNDIS EP N Size Register (USB1GENRNDISEPn)

15.5.2.2.16 USB1 Auto Req Register (USB1AUTOREQ)

The USB1 auto req register (USB1AUTOREQ) allows the CPU to enable an automatic IN token request generation for host mode RX operation per each RX endpoint. This features has the DMA set the ReqPkt bit in the RXCSR when it clears the RxPktRdy bit after reading out a packet. The ReqPkt bit is used by the core to generate an IN token to receive data. By using this feature, the host can automatically generate an IN token after the DMA finishes receiving data and empties an endpoint buffer, thus receiving the next data packet as soon as possible from the connected device. Without this feature, the CPU will have to manually set the ReqPkt bit for every USB packet.

There are two modes that Auto Req can function: always or all except an EOP. The always mode will set the ReqPkt bit after every USB packet the DMA receives thus generating a new IN token after each USB packet. The EOP mode will set the ReqPkt bit after every USB packet that isn't an EOP (end of packet) in the CPPI descriptor. For RNDIS, CDC, and Generic RNDIS modes the auto req will stop when the EOP is received (either via a short packet for RNDIS,CDC, and Generic RNDIS or the count is reached for Generic RNDIS), making it useful for starting a large RNDIS packet and having it auto generate IN tokens until the end of the RNDIS packet. For transparent mode, every USB packet is an EOP CPPI packet, so the auto req never functions and acts like auto req is disabled.

The USB1 auto req register is shown in Figure 15-102 and described in Table 15-112.

15.5.2.2.17 USB1 SRP Fix Time Register (USB1SRPFIXTIME)

The USB1 SRP fix time register (USB1SRPFIXTIME) allows the CPU to configure the maximum amount of time the SRP fix logic blocks the AVAID from the PHY to the OTG core. This time allows the VBUS signal the ability to get below the thresholds and therefore remove the chance of voltage bounces which could give false threshold measurements.

The USB1 SRP fix time register is shown in Figure 15-103 and described in Table 15-113.

Figure 15-103. USB1 SRP Fix Time Register (USB1SRPFIXTIME)

Bits	Field	Description
31-0	srpfixtime	SRP Fix maximum time in 60 MHz cycles. Default is 700 ms.

15.5.2.2.18 USB1 Teardown Register (USB1TDOWN)

The USB1 teardown register (USB1TDOWN) controls the tearing down of rx and tx fifos in the USB controller. When a '1' is written to a valid bit in this register, the CPPI FIFO pointers for that endpoint are cleared , and the register automatically clears itself after 1 clock cycle. This register must be used in conjunction with the CPPI DMA Teardown mechanism. The Host should also write the FlushFIFO bits in the TXCSR and RXCSR Mentor USB Controller registers to ensure a complete teardown of the endpoint. See the Mentor specification for details.

The USB1 teardown register is shown in Figure 15-104 and described in Table 15-114.

15.5.2.2.19 USB1 PHY UTMI Register (USB1UTMI)

The USB1 PHY UTMI register (USB1UTMI) controls various PHY UTMI signals. The UTMI interface is located between the PHY module and the Mentor Graphics Controller. These signals are inputs to the PHY but are not outputs from the Mentor Graphics Controller. It is important to set the otgdisable bit in to a high value to operate the PHY in a non-OTG mode.

The USB1 PHY UTMI register is shown in Figure 15-105 and described in Table 15-115.

15.5.2.2.20 USB1 MGC UTMI Loopback Register (USB1UTMILB)

The USB1 MGC UTMI loopback register (USB1UTMILB) contains most of the input and output UTMI signals for the Mentor Graphics Controller. The UTMI interface is located between the PHY module and the Mentor Graphics Controller.

In the loopback mode test register bits 11 to 0 control various UTMI signals that are input to the Mentor Graphics Controller.

In the loopback mode test register bits 28 to 16 observe various UTMI signals that are output from the Mentor Graphics Controller.

The USB1 MGC UTMI loopback register is shown in Figure 15-106 and described in Table 15-116.

15.5.2.2.21 USB1 Mode Register (USB1MODE)

The USB1 mode register (USB1MODE) allows the user a flexibility of controlling the role that the controller assumes. Via the setting of the USB1MODE[Bit7=Iddig_Mux], the user has the capability of allowing the control to be coming from a register field (USB1MODE[Bit8=iddig]) or from the USB_ID pin which is indirectly controlled by the cable end. if USB1MODE[iddig_mux]=0, the state of the USB_ID pin controls the role the controller assumes. However, if USB1MODE[Iddig_mux]=1, then the setting USB1MODE[iddig] will control the role the controller assumes.

The loopback bit enables the loopback test. This test allows MGC1 to be connected to MGC0. It is important to set both loopback bits in both USB0/1 Mode registers. The USB0 MGC UTMI Loopback Register contains the various UTMI signals to be controlled and observed during loopback test.

The phy_test bit enables the phy_test mode. This test mode is intended to allow additional control of the UTMI inputs to the PHY. Currently, these inputs are drvvbus, dppulldown, dmpulldown, and idpullup. When phy_test is high, then the pin inputs for these signals control the inputs to the PHY instead of the Mentor controller outputs. The phy_test mode is not active with loopback mode is active.

When phy_test is active than the PHY inputs datainh is equal to datain. And txvalidh is equal to txvalid.

The USB1 mode register is shown in Figure 15-107 and described in Table 15-117.

15.5.2.2.22 USB1 Mentor Core Registers

A description of the mentor core registers is available in Section 15.5.6. Two instantiations of the USB core exists, USB0 and USB1. These registers reside back to back within USB0 space. The core registers that are used by USB0 subsystem are defined within offsets 1400h-159Ch, while the core registers that are used by USB1 subsystem are defined within offsets 1C00h–1D9Ch.

15.5.3.3 CPPI DMA Emulation Control Register (DMAEMU)

The CPPI DMA emulation control register (DMAEMU) is used to control the behavior of the DMA when the emususp input is asserted. The CPPI DMA emulation control register is shown in Figure 15-110 and described in Table 15-121.

Figure 15-110. CPPI DMA Emulation Control Register (DMAEMU)

31	2	1	0
Reserved		soft	free
R-0h		R/W-0h	R/W-0h

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 15-121. CPPI DMA Emulation Control Register (DMAEMU) Field Descriptions

Bits	Field	Value	Description
31-2	Reserved	0	Always read as 0. Writes have no effect.
1	soft		Control for emulation pause request
		0	Forces emu_pause_req low
		1	Does not force emu_pause_req low
0	free		Enable for emulation suspend

15.5.3.4 4.3.28 CPPI Mem1 Base Address Register (DMAMEM1BA)

The CPPI Mem1 base address register (DMAMEM1BA) is the base address for the CPPI mem1 accesses. This base address points to the location of the data that will be transferred from external memory to the USB DMA ram. This 16-bit field is the most significant 16-bits of the 32-bit base address.

The CPPI Mem1 base address register is shown in Figure 15-111 and described in Table 15-122.

Figure 15-111. CPPI Mem1 Base Address Register (DMAMEM1BA)

31 16	15 0

15.5.3.5 4.3.28 CPPI Mem1 Mask Address Register (DMAMEM1MASK)

The CPPI Mem1 mask address register (DMAMEM1MASK) is the mask address for the CPPI mem1 base register. The 16-bit mem1_mask register will be ANDed with the 16-bit mem1_base register. The 16-bit resultant signal is the most significant 16-bits of the 32-bit address for external memory accesses during DMA transactions.

The CPPI Mem1 mask address register is shown in Figure 15-112 and described in Table 15-123.

Figure 15-112. CPPI Mem1 Mask Address Register (DMAMEM1MASK)

31–16	15–0
mem1_mask	Reserved
R/W-0000h	R/-0h

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 15-123. CPPI Mem1 Mask Address Register (DMAMEM1MASK) Field Descriptions

Bits	Field	Description
31-16	mem1_mask	CPPI mem1 mask address
15-0	Reserved	Always read as 0. Writes have no effect.

15.5.3.6 Tx Channel N Global Configuration Register (TXGCRn)

The Tx channel N global configuration register (TXGCRn) are used to initialize the behavior of each of the Tx CPPI DMA channels. N,n ranges from 0 to 14. The Tx channel N global configuration register is shown in Figure 15-113 and described in Table 15-124.

Figure 15-113. Tx Channel N Global Configuration Register (TXGCRn)

31	30	29–16
tx_enable	tx_teardown	Reserved
R/W-0h	R/W	R

15.5.3.7 Rx Channel N Global Configuration Register (RXGCRn)

The Rx channel global configuration registers are used to initialize the global (non descriptor type specific) behavior of each of the Rx CPPI DMA channels. If the enable bit is being set, the Rx Channel Global Configuration Register should only be written after all of the other Rx Configuration Registers have been initialized. N,n ranges from 0 to 14.

The Rx channel N global configuration register is shown in Figure 15-114 and described in Table 15-125

Figure 15-114. Rx Channel N Global Configuration Register (RXGCRn)

31	30	29 – 25	24
rx_enable	rx_teardown	Reserved	rx_error_handling
R/W-0h	R/W	R	W

23 – 16
rx_sop_offset
W

15 – 14	13 – 12	11 – 8
rx_default_desc_type	rx_default_rq_qmgr	rx_default_rq_qnum
W	W	W

7 – 0
rx_default_rq_qnum
W

LEGEND: R/W = Read/Write; R = Read only; W = Write only; -*n* = value after reset

Table 15-125. Rx Channel N Global Configuration Register (RXGCRn) Field Descriptions

Bits	Field Name	Value	Description
31	rx_enable		This field enables or disables the channel
		0	Channel is disabled
		1	Channel is enabled
			This field will be cleared after a channel teardown is complete.
30	rx_teardown		This field indicates whether or not an Rx teardown operation is complete. This field should be cleared when a channel is initialized. This field will be set after a channel teardown is complete.
29-25	Reserved		Reserved
24	rx_error_handling		This bit controls the error handling mode for the channel and is only used when channel errors (i.e. descriptor or buffer starvation occurs):
		0	Starvation errors result in dropping packet and reclaiming any used descriptor or buffer resources back to the original queues/pools they were allocated to
		1	Starvation errors result in subsequent re-try of the descriptor allocation operation. In this mode, the DMA will return to the IDLE state without saving it's internal operational state back to the internal state RAM and without issuing an advance operation on the FIFO interface. This results in the DMA re-initiating the FIFO block transfer at a later time with the intention that additional free buffers and/or descriptors will have been added.
			Regardless of the value of this bit, the DMA will assert the cdma_rx_sof_overrun (for SOP) or cdma_rx_mof_overrun (for non-SOP) when
23:16	rx_sop_offset		This field specifies the number of bytes that are to be skipped in the SOP buffer before beginning to write the payload. This value must be less than the minimum size of a buffer in the system. Valid values are 0 – 255 bytes.
15-14	rx_default_desc_type		This field indicates the default descriptor type to use:
		0	Reserved
		1	Host
		2	Reserved
		3	Reserved
			The actual descriptor type that will be used for reception can be overridden by information provided in the CPPI FIFO data block.

Table 15-130. CPPI DMA Scheduler Table Word N (WORDn) Field Descriptions

Bits	Field Name	Value	Description
31	entry3_rxtx		This bit indicates if this entry is for a Tx or an Rx channel and is encoded as follows:
		0	Tx Channel
		1	Rx Channel
30-29	Reserved		Reserved
28-24	entry3_channel		This field indicates the channel number that is to be given an opportunity to transfer data. If this is a Tx entry, the DMA will be presented with a scheduling 'credit' for that exact Tx channel. If this is an Rx entry, the DMA will be presented with a scheduling credit for the Rx FIFO that is associated with this channel. For Rx FIFOs which carry traffic for more than 1 Rx DMA channel, the exact channel number that is given in the Rx credit will actually be the channel number which is currently on the head element of that Rx FIFO, which is not necessarily the channel number given in the scheduler table entry.
23	entry2_rxtx		This bit indicates if this entry is for a Tx or an Rx channel and is encoded as follows:
		0	Tx Channel
		1	Rx Channel
22-21	Reserved		Reserved
20-16	entry2_channel		This field indicates the channel number that is to be given an opportunity to transfer data. If this is a Tx entry, the DMA will be presented with a scheduling 'credit' for that exact Tx channel. If this is an Rx entry, the DMA will be presented with a scheduling credit for the Rx FIFO that is associated with this channel. For Rx FIFOs which carry traffic for more than 1 Rx DMA channel, the exact channel number that is given in the Rx credit will actually be the channel number which is currently on the head element of that Rx FIFO, which is not necessarily the channel number given in the scheduler table entry.
15	entry1_rxtx		This bit indicates if this entry is for a Tx or an Rx channel and is encoded as follows:
		0	Tx Channel
		1	Rx Channel
14:-13	Reserved

15.5.5.12 Queue Manager Linking RAM Region 0 Base Address Register (LRAM0BASE)

The Linking RAM region 0 base address register is used to set the base address for the first portion of the Linking RAM. This address must be 32-bit aligned. It is used by the Queue Manager to calculate the 32-bit linking address for a given descriptor index. It does not support byte accesses.

The Linking RAM region 0 base address register is shown in Figure 15-130 and described in Table 15-143.

Figure 15-130. Queue Manager Linking RAM Region 0 Base Address Register (LRAM0BASE)

31	0
region0_base	
R/W-0h	

LEGEND: R/W = Read/Write; R = Read only; RC = Read Clear; -*n* = value after reset

Bits	Field Name	Description
31-0	region0_base	This field stores the base address for the first region of the linking RAM. This may be anywhere in 32-bit address space but would be typically located in on-chip memory.

15.5.5.13 Queue Manager Linking RAM Region 0 Size Register (LRAM0SIZE)

The Linking RAM region 0 size register is used to set the size of the array of linking pointers that are located in Region 0 of Linking RAM. The size specified the number of descriptors for which linking information is stored in this region. It does not support byte accesses.

The Linking RAM region 0 size register is shown in Figure 15-131 and described in Table 15-144.

Figure 15-131. Queue Manager Linking RAM Region 0 Size Register (LRAM0SIZE)

31 14	13 0
Reserved	region0_size

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 15-144. Queue Manager Linking RAM Region 0 Size Register (LRAM0SIZE) Field Descriptions

Bits	Field Name	Description
31-14	Reserved	Reserved
13-0	region0_size	This field indicates the number of entries that are contained in the linking RAM region 0. A descriptor with index less than region0_size value has its linking location in region 0. A descriptor with index greater than region0_size has its linking location in region 1. The queue manager will add the index (left shifted by 2 bits) to the appropriate regionX_base_addr to get the absolute 32-bit address to the linking location for a descriptor.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

15.5.5.14 Queue Manager Linking RAM Region 1 Base Address Register (LRAM1BASE)

The Linking RAM region 1 base address register is used to set the base address for the second portion of the Linking RAM. This base address is used by the Queue Manager to calculate the 32-bit linking address from the descriptor index. All descriptors with index higher than that given in Linking RAM 0 Size register have linking information stored in linking RAM region 1. It does not support byte accesses.

The Linking RAM region 1 base address register is shown in Figure 15-132 and described in Table 15-145.

15.5.5.22 Queue Manager Queue N Register A (CTRLAn)

The queue N register A is an optional register that is only implemented for a queue if the queue supports entry/byte count feature. The entry count feature provides a count of the number of entries that are currently valid in the queue. It does not support byte accesses. N ranges from 0 to 155.

The queue N register A is shown in Figure 15-140 and described in Table 15-153.

Figure 15-140. Queue Manager Queue N Register A (CTRLAn)

31–14	13–0

Table 15-153. Queue Manager Queue N Register A (CTRLAn) Field Descriptions

Bits	Field Name	Description
31-14	Reserved	Reserved
13-0	queue_entry_count	This field indicates how many packets are currently queued on the queue. This count is incremented by 1 whenever a packet is added to the queue. This count is decremented by 1 whenever a packet is popped from the queue.

15.5.5.23 Queue Manager Queue N Register B (CTRLBn)

The Queue N Register B is an optional register that is only implemented for a queue if the queue supports a total byte count feature. The total byte count feature provides a count of the total number of bytes in all of the packets that are currently valid in the queue. This register must be read prior to reading Queue N register D during packet pop operation if the total size information is desired. It does not support byte accesses. N ranges from 0 to 155.

The queue N register B is shown in Figure 15-141 and described in Table 15-154.

15.5.5.24 Queue Manager Queue N Register C (CTRLCn)

The Queue N Register C is used to provide additional information about the packet that is being pushed or popped from the queue. This register provides an option for the packet to be pushed onto either the tail of the queue (default) or the head of the queue (override). This register must be written prior to writing the Queue N register D during packet write operations. This register must be read prior to reading Queue N register D during pop operations if the packet size information is desired. It does not support byte accesses. N ranges from 0 to 155.

The queue N register C is shown in Figure 15-142 and described in Table 15-155.

Figure 15-142. Queue Manager Queue N Register C (CTRLCn)

15.5.6 USB Mentor Core Registers

The Mentor Control register map is divided into the following sections:

- **Common USB registers (0h–Fh)** – These registers provide control and status for the complete core.
- **Indexed Endpoint Control/Status registers (10h–1Fh)** – These registers provide control and status for the currently selected endpoint. The registers mapped into this section depend on whether the core is in Peripheral mode or in Host mode and on the value of the Index register.
- **FIFOs (20h–5Fh)** – This address range provides access to the endpoint FIFOs.
- Additional Control and Configuration registers (60h–7Fh) – These registers provide additional device status and control.
- **Target Endpoint Control Registers (80h–FFh)** – These registers provide target function and hub address details for each of the endpoints.
- **Non-Indexed Endpoint Control/Status registers (100h and above)** – The registers available at 10h–1Fh, accessible independently of the setting of the Index register. 100h–10Fh, EP0 registers; 110h–11Fh, EP1 registers; 120h–12Fh, EP2; and so on.

Two instances of the Mentor Core registers exist within USB0 space. Since both USB modules operate independent of each other, each USB core has its own set of registers. USB0 Mentor Base Address is 0x4740_1400 while USB1 Mentor Core Registers Base address is 0x4740_1C00. Below offset of the core registers The absolute address is computed by summing the CORE_OFFSET with USBn_OFFSET.

15.5.6.1 Common USB Registers

These registers provide control and status for the complete core. Table 15-160 lists the registers.

Table 15-160. Common USB Registers

Core Address Offset	Common USB Registers
0h	Function Address Register
1h	Power Management Register
2h	Interrupt Register for Endpoint 0 Plus Transmit Endpoints 1 to 15
4h	Interrupt Register for Receive Endpoints 1 to 15
6h	Interrupt Enable Register for INTRTX
8h	Interrupt Enable Register for INTRRX
Ah	Interrupt Register for Common USB Interrupts
Bh	Interrupt Enable Register for INTRUSB
Ch	Frame Number Register
Eh	Index Register for Selecting the Endpoint Status and Control Registers
Fh	Register to Enable the USB 2.0 Test Modes

15.5.6.1.1 Function Address Register (USBn_FADDR)

The function address register (USBn_FADDR) is an 8-bit register that should be written with the 7-bit address of the peripheral part of the transaction.

Since USB cores are configured with multipoint support, this register only applies to operations carried out when the controller is in peripheral mode. In Host mode, this register is ignored.

The function address register is shown in Figure 15-147 and described in Table 15-161.

Figure 15-147. Function Address Register (USBn_FADDR)

7	6	0
Reserved	FUNCADDR	
R-0h	W-0-7Fh	

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 15-161. Function Address Register (USBn_FADDR) Field Descriptions

Bits	Field Name	Description
7	Reserved	Reserved
6-0	FUNCADDR	7_bit address of the peripheral part of the transaction. When used in peripheral mode, this register should be written with the address received through a SET_ADDRESS command, which is then used for decoding the function address in subsequent token packets.

15.5.6.1.2 Power Management Register (USBn_POWER)

The power management register (USBn_POWER) is an 8-bit register that is used for controlling suspend and resume signaling, and some basic operational aspects of the USB core. This register is shown in Figure 15-148 and described in Table 15-162.

Figure 15-148. Power Management Register (USBn_POWER)

7	6	5	4	3	2	1	0
ISOUPDATE	SOFTCONN	HSEN	HSMODE	RESET	RESUME	SUSPENDM	ENSUSPM
R/W-0-1h	R/W-0-1h	R/W-0-1h	R/W-0-1h	R/W-0-1h	R/W-0-1h	R/W-0-1h	R/W-0-1h

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 15-162. Power Management Register (USBn_POWER) Field Descriptions

Bits	Field Name	Description
7	ISOUPDATE	When set, the USB controller will wait for an SOF token from the time TxPktRdy is set before sending the packet. If an IN token is received before an SOF token, then a zero length data packet will be sent. Note: this is only valid in Peripheral Mode. This bit only affects endpoints performing Isochronous transfers.
6	SOFTCONN	If Soft Connect/Disconnect feature is enabled, then the USB D+/D-lines are enabled when this bit is set and tri-stated when this bit is cleared. Note: This is only valid in Peripheral Mode.
5	HSEN	When set, the USB controller negotiates for high-speed mode when the device is reset by the hub. If not set, the device will only operate in full-speed mode.
4	HSMODE	This bit is set when the USB controller has successfully negotiated for high-speed mode.
3	RESET	This bit is set when reset signaling is present on the bus. Note: this bit is Read/Write in Host Mode, but read-only in peripheral mode.
2	RESUME	Set to generate resume signaling when the controller is in suspend mode. The bit should be cleared after 10 ms (a maximum of 15 ms) to end resume signaling. In Host mode, this bit is also automatically set when resume signaling from the target is detected while the USB controller is suspended.
1	SUSPENDM	In Host mode, this bit should be set to enter suspend mode. In peripheral mode, this bit is set on entry into suspend mode. It is cleared when the interrupt register is read, or the RESUME bit is set.
0	ENSUSPM	Set to enable the SUSPENDM output.

15.5.6.1.3 Interrupt Register for Endpoint 0 Plus Transmit Endpoints 1 to 15 (USBn_INTRTX)

The interrupt register for endpoint 0 plus transmit endpoints 1 to 15 (USBn_INTRTX) is a 16-bit read-only register that indicates which interrupts are currently active for endpoint 0 and the TX endpoints 1–15. Note also that all active interrupts are cleared when this register is read.

The interrupt register for endpoint 0 plus transmit endpoints 1 to 15 is shown in Figure 15-149 and described in Table 15-163.

15.5.6.1.4 Interrupt Register for Receive Endpoints 1 to 15 (INTRRX)

The interrupt register for receive endpoints 1 to 15 (INTRRX) is a 16-bit read-only register that indicates which of the interrupts for Rx Endpoints 1 – 15 are currently active. Note also that all active interrupts are cleared when this register is read.

The interrupt register for receive endpoints 1 to 15 is shown in Figure 15-150 and described in Table 15-164.

15.5.6.1.6 Interrupt Enable Register for INTRRX (INTRRXE)

The interrupt enable register for INTRRX (INTRRXE) is a 16-bit register that provides interrupt enable bits for the interrupts in USBn_INTRRX. On reset, the bits corresponding to the Rx endpoints are set to 1. This register is shown in Figure 15-152 and described in Table 15-166.

Figure 15-152. Interrupt Enable Register for INTRRX (INTRRXE)

15.5.6.1.7 Interrupt Register for Common USB Interrupts (USBn_INTRUSB)

The interrupt register for common USB interrupts (USBn_INTRUSB) is an 8-bit read-only register that indicates which USB interrupts are currently active. All active interrupts will be cleared when this register is read. This register is shown in Figure 15-153 and described in Table 15-167.

Figure 15-153. Interrupt Register for Common USB Interrupts (USBn_INTRUSB)

7	6	5	4	3	2	1	0

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 15-167. Interrupt Register for Common USB Interrupts (USBn_INTRUSB) Field Descriptions

Bits	Field Name	Description
7	VBUSERR	Set when VBus drops below the VBus valid threshold during a session. Only valid when the USB controller is 'A' device. All active interrupts will be cleared when this register is read.
6	SESSREQ	Set when session request signaling has been detected. Only valid when USB controller is 'A' device.
5	DISCON	Set in host mode when a device disconnect is detected. Set in peripheral mode when a session ends.
4	CONN	Set when a device connection is detected. Only valid in host mode.
3	SOF	Set when a new frame starts.
2	RESET_BABBLE	Set in peripheral mode when reset signaling is detected on the bus set in host mode when babble is detected.
1	RESUME	Set when resume signaling is detected on the bus while the USB controller is in suspend mode.
0	SUSPEND	Set when suspend signaling is detected on the bus only valid in peripheral mode.

15.5.6.1.8 Interrupt Enable Register for INTRUSB (USBn_INTRUSBE)

The interrupt enable register for INTRUSB (USBn_INTRUSBE) is an 8-bit register that provides interrupt enable bits for each of the interrupts in USBn_INTRUSB. This register is shown in Figure 15-154 and described in Table 15-168.

Figure 15-154. Interrupt Enable Register for INTRUSB (USBn_INTRUSBE)

15.5.6.1.9 Frame Number Register (USBn_FRAME)

The frame number register (USBn_FRAME) is a 16-bit read-only register that holds the last received frame number. This register is shown in Figure 15-155 and described in Table 15-169.

Figure 15-155. Frame Number Register (USBn_FRAME)

15–11	10–0
Reserved	FRAMENUMBER
R-0h	R-0-7FFh

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 15-169. Frame Number Register (USBn_FRAME) Field Descriptions

Bits	Field Name	Description
15-11	Reserved	Reserved
10-0	FRAMENUMBER	Last received frame number

15.5.6.1.10 Index Register for Selecting the Endpoint Status and Control Registers (USBn_INDEX)

Each TX endpoint and each Rx endpoint have their own set of control/status registers located between Core_Offset 0x0100 – 0x01FF. In addition one set of TX control/status and one set of Rx control/status registers appear at Core_Offset 0x0010 – 0x0019. This block of memory can be used as a proxy to access endpoint configuration registers. Index is a 4-bit register that determines which endpoint control/status registers are accessed.

Before accessing an endpoint's control/status registers at Core_Offset 0x0010 – 0x0019, the endpoint number should be written to the Index register to ensure that the correct control/status registers appear in the memory map.

The index register for selecting the endpoint status and control registers is shown in Figure 15-156 and described in Table 15-170.

Figure 15-156. Index Register for Selecting the Endpoint Status and Control Registers (USBn_INDEX)

7–4	3–0
Reserved	EPSEL
R-0h	R/W-0-Fh

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 15-170. Index Register for Selecting the Endpoint Status and Control Registers (USBn_INDEX) Field Descriptions

Bits	Field Name	Description
7-4	Reserved	Reserved
3-0	EPSEL	Each transmit endpoint and each receive endpoint have their own set of control/status registers. EPSEL determines which endpoint control/status registers are accessed. Before accessing an endpoint's control/status registers, the endpoint number should be written to the Index register to ensure that the correct control/status registers appear in the memory-map.

15.5.6.1.11 Register to Enable the USB 2.0 Test Modes (USBn_TESTMODE)

The register to enable the USB 2.0 test modes (USBn_TESTMODE) is an 8-bit register that is primarily used to put the USB controller into one of the four test modes for high-speed operation described in the USB 2.0 specification – in response to a SET FEATURE: TESTMODE command. It is not used in normal operation.

The register to enable the USB 2.0 test modes is shown in Figure 15-157 and described in Table 15-171.

Figure 15-157. Register to Enable the USB 2.0 Test Modes (USBn_TESTMODE)

7	6	5	4	3	2	1	0
FORCE_HOST	FIFO_ACCESS	FORCE_FS	FORCE_HS	TEST_PACKET	TEST_K	TEST_J	TEST_SE0_NAK
R/W-0-1h	W-0-1h	R/W-0-1h	R/W-0-1h	R/W-0-1h	R/W-0-1h	R/W-0-1h	R/W-0-1h

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 15-171. Register to Enable the USB 2.0 Test Modes (USBn_TESTMODE) Field Descriptions

Bits	Field Name	Description
7	FORCE_HOST	Set this bit to forcibly put the USB controller into Host mode when SESSION bit is set, regardless of whether it is connected to any peripheral. The controller remains in Host mode until the session bit is cleared, even if a device is disconnected. And if the FORCE_HOST but remains set, it re-enters Host mode next time the SESSION bit is set. The operating speed is determined using the FORCE_HS and FORCE_FS bits.
6	FIFO_ACCESS	Set this bit to transfer the packet in EP0 Tx FIFO to EP0 Receive FIFO. It is cleared automatically.
5	FORCE_FS	Set this bit to force the USB controller into full-speed mode when it receives a USB reset.
4	FORCE_HS	Set this bit to force the USB controller into high-speed mode when it receives a USB reset.
3	TEST_PACKET	Set this bit to enter the Test_Packet test mode. In this mode, the USB controller repetitively transmits a 53-byte test packet on the bus, the form of which is defined in the Universal Serial Bus Specification Revision 2.0. Note: The test packet has a fixed format and must be loaded into the endpoint 0 FIFO before the test mode is entered.
2	TEST_K	Set this bit to enter the Test_K test mode. In this mode, the USB controller transmits a continuous K on the bus.
1	TEST_J	Set this bit to enter the Test_J test mode. In this mode, the USB controller transmits a continuous J on the bus.
0	TEST_SE0_NAK	Set this bit to enter the Test_SE0_NAK test mode. In this mode, the USB controller remains in high-speed mode, but responds to any valid IN token with a NAK.

15.5.6.2 Indexed Register Space

This is a block of the core register space that is used as a proxy to access the configuration and status registers of an endpoint. Mapping is done by programming the INDEX register with the endpoint number. Table 15-172 lists the registers.

Table 15-172. Indexed Region Registers

Core Address Offset	Indexed Region Registers
10h	Maximum Packet Size for Peripheral/Host Transmit Endpoint
12h	Control Status Register for Endpoint 0 in Peripheral Mode
12h	Control Status Register for Endpoint 0 in Host Mode
12h	Control Status Register for Peripheral Transmit Endpoint
12h	Control Status Register for Host Transmit Endpoint
14h	Maximum Packet Size for Peripheral/Host Receive Endpoint
16h	Control Status Register for Peripheral Receive Endpoint
16h	Control Status Register for Host Receive Endpoint
18h	Count 0 Register
18h	Receive Count Register
1Ah	Type Register (Host mode only)
1Ah	Transmit Type Register (Host mode only)
1Bh	NAKLimit0 Register (Host mode only)
1Bh	Transmit Interval Register (Host mode only)
1Ch	Receive Type Register (Host mode only)
1Dh	Receive Interval Register (Host mode only)
1Fh	Configuration Data Register

15.5.6.2.1 Maximum Packet Size for Peripheral/Host Transmit Endpoint Register (USBn_TXMAXP)

The maximum packet size for peripheral/host transmit endpoint register (USBn_TXMAXP) defines the maximum amount of data that can be transferred through the selected Tx endpoint in a single operation. There is a TxMaxP register for each Tx endpoint (except Endpoint 0). Endpoint 0 resource is hardened in design and max packet size is set to 64 bytes and no user configuration is required or does not exist.

The maximum packet size for peripheral/host transmit endpoint register is shown in Figure 15-158 and described in Table 15-173.

Figure 15-158. Maximum Packet Size for Peripheral/Host Transmit Endpoint Register (USBn_TXMAXP)

15 – 11	10 – 0
Reserved	MAXPAYLOAD
R-0h	R/W-0-400h

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 15-173. Maximum Packet Size for Peripheral/Host Transmit Endpoint (USBn_TXMAXP) Field Descriptions

Bits	Field Name	Description
15-11	Reserved	Reserved
10-0	MAXPAYLOAD	The maximum payload transmitted in a single transaction. The value set can be up to 1024 bytes, but is subject to the constraints placed by the USB specification on packet sizes for bulk, interrupt, and isochronous transfers in full-speed and high-speed operations. The value written to this register should match the wMaxPacketSize field of the standard endpoint descriptor for the associated endpoint. A mismatch could cause unexpected results.

15.5.6.2.2 Control Status Register for Endpoint 0 in Peripheral Mode (USBn_PERI_CSR0)

The control status register for endpoint 0 in peripheral mode (USBn_PERI_CSR0) is a 16-bit register that provides control and status bits for endpoint 0 when USB controller assumes the role of a peripheral. This register is shown in Figure 15-159 and described in Table 15-174.

Figure 15-159. Control Status Register for Endpoint 0 in Peripheral Mode (USBn_PERI_CSR0)

15						9	8

W-0-1h	W-0-1h	W-0-1h	R-0-1h	W-0-1h	R/W-0-1h	R/W-0-1h	R-0h

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 15-174. Control Status Register for Endpoint 0 in Peripheral Mode (USBn_PERI_CSR0) Field Descriptions

Bits	Field Name	Description
15-9	Reserved	Reserved
8	FLUSHFIFO	Set this bit to flush the next packet to be transmitted/read from the endpoint 0 FIFO. The FIFO pointer is reset and the TXPKTRDY/RXPKTRDY bit is cleared. Note: FLUSHFIFO has no effect unless TXPKTRDY/RXPKTRDY is set.
7	SERV_SETUPEND	Set this bit to clear the SETUPEND bit. It is cleared automatically.
6	SERV_RXPKTRDY	Set this bit to clear the RXPKTRDY bit. It is cleared automatically.
5	SENDSTALL	Set this bit to terminate the current transaction. The STALL handshake will be transmitted and then this bit will be cleared automatically.
4	SETUPEND	This bit will be set when a control transaction ends before the DATAEND bit has been set. An interrupt is generated, and the FIFO will be flushed at this time. The bit is cleared by the writing a 1 to the SERV_SETUPEND bit.
3	DATAEND	Set this bit to 1: a. When setting TXPKTRDY for the last data packet. b. When clearing RXPKTRDY after unloading the last data packet. c. When setting TXPKTRDY for a zero length data packet. It is cleared automatically.
2	SENTSTALL	This bit is set when a STALL handshake is transmitted. This bit should be cleared.
1	TXPKTRDY	Set this bit after loading a data packet into the FIFO. It is cleared automatically when the data packet has been transmitted. An interrupt is generated (if enabled) when the bit is cleared.
0	RXPKTRDY	This bit is set when a data packet has been received. An interrupt is generated when this bit is set. This bit is cleared by setting the SERV_RXPKTRDY bit.

Table 15-175. Control Status Register for Endpoint 0 in Host Mode (USBn_HOST_CSR0) Field Descriptions

Bits	Field Name	Description
15-12	Reserved	Reserved
11	DSPING	The CPU writes a 1 to the DSPING bit to instruct the core not to issue PING tokens in the data and status phases of a high-speed control transfer (for use with devices that do not respond to PING).
10	DATATOGWREN	Write 1 to this bit to enable the DATATOG bit to be written. This bit is automatically cleared once the new value is written to DATATOG.
9	DATATOG	When read, this bit indicates the current state of the EP0 data toggle. If DATATOGWREN is high, this bit can be written with the required setting of the data toggle. If DATATOGWREN is low, any value written to this bit is ignored.
8	FLUSHFIFO	Write 1 to this bit to flush the next packet to be transmitted/read from the Endpoint 0 FIFO. The FIFO pointer is reset and the TXPKTRDY/RXPKTRDY bit is cleared. Note: FLUSHFIFO has no effect unless TXPKTRDY/RXPKTRDY is set.
7	NAK_TIMEOUT	This bit will be set when endpoint 0 is halted following the receipt of NAK responses for longer than the time set by the NAKLIMIT0 register. This bit should be cleared to allow the endpoint to continue.
6	STATUSPKT	Set this bit at the same time as the TXPKTRDY or REQPKT bit is set, to perform a status stage transaction. Setting this bit ensures that the data toggle is set so that a DATA1 packet is used for the Status Stage transaction.
5	REQPKT	Set this bit to request an IN transaction. It is cleared when RXPKTRDY is set.
4	ERROR	This bit is set when three attempts have been made to perform a transaction with no response from the peripheral. You should clear this bit. An interrupt is generated when this bit is set.
3	SETUPPKT	Set this bit, at the same time as the TXPKTRDY bit is set, to send a SETUP token instead of an OUT token for the transaction.
2	RXSTALL	This bit is set when a STALL handshake is received. You should clear this bit.
1	TXPKTRDY	Set this bit after loading a data packet into the FIFO. It is cleared automatically when the data packet has been transmitted. An interrupt is generated (if enabled) when the bit is cleared.
0	RXPKTRDY	This bit is set when a data packet has been received. An interrupt is generated when this bit is set. Clear this bit by setting the SERV_RXPKTRDY bit.

15.5.6.2.4 Control Status Register for Peripheral Transmit Endpoint (USBn_PERI_TXCSR)

The control status register for peripheral transmit endpoint (USBn_PERI_TXCSR) is a 16-bit register that provides control and status bits for transfers through the currently-selected Tx endpoint when controller assumes the role of a peripheral. There is a TXCSR register for each configured Tx endpoint (not including Endpoint 0).

The control status register for peripheral transmit endpoint is shown in Figure 15-161 and described in Table 15-176.

Figure 15-161. Control Status Register for Peripheral Transmit Endpoint (USBn_PERI_TXCSR)

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 15-176. Control Status Register for Peripheral Transmit Endpoint (USBn_PERI_TXCSR) Field Descriptions

Bits	Field Name	Description
15	AUTOSET	DMA Mode: The CPU needs to set the AUTOSET bit prior to enabling the Tx DMA. CPU Mode: If the CPU sets the AUTOSET bit, the TXPKTRDY bit will be automatically set when data of the maximum packet size (value in TXMAXP) is loaded into the Tx FIFO. If a packet of less than the maximum packet size is loaded, then the TXPKTRDY bit will have to be set manually.
14	ISO	Set this bit to enable the Tx endpoint for Isochronous transfers, and clear it to enable the Tx endpoint for Bulk or Interrupt transfers.
13	MODE	Set this bit to enable the endpoint direction as Tx, and clear the bit to enable it as Rx. Note: This bit has any effect only where the same endpoint FIFO is used for both Transmit and Receive transactions.
12	DMAEN	Set this bit to enable the DMA request for the Tx endpoint.
11	FRCDATATOG	Set this bit to force the endpoint data toggle to switch and the data packet to be cleared from the FIFO, regardless of whether an ACK was received. This can be used by Interrupt Tx endpoints that are used to communicate rate feedback for Isochronous endpoints.
10	DMAMODE	This bit should always be set to 1 when the DMA is enabled.
9-7	Reserved	Reserved
6	CLRDATATOG	Write a 1 to this bit to reset the endpoint data toggle to 0.
5	SENTSTALL	This bit is set automatically when a STALL handshake is transmitted. The FIFO is flushed and the TXPKTRDY bit is cleared. You should clear this bit.
4	SENDSTALL	Write a 1 to this bit to issue a STALL handshake to an IN token. Clear this bit to terminate the stall condition. Note: This bit has no effect where the endpoint is being used for Isochronous transfers.
3	FLUSHFIFO	Write a 1 to this bit to flush the next packet to be transmitted from the endpoint Tx FIFO. The FIFO pointer is reset and the TXPKTRDY bit is cleared. Note: FlushFIFO has no effect unless the TXPKTRDY bit is set. Also note that, if the FIFO is double-buffered, FlushFIFO may need to be set twice to completely clear the FIFO.
2	UNDERRUN	This bit is set automatically if an IN token is received when TXPKTRDY is not set. You should clear this bit.
1	FIFONOTEMPTY	This bit is set when there is at least 1 packet in the Tx FIFO. You should clear this bit.
0	TXPKTRDY	Set this bit after loading a data packet into the FIFO. It is cleared automatically when a data packet has been transmitted. An interrupt is generated (if enabled) when the bit is cleared.

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 15-177. Control Status Register for Host Transmit Endpoint (USBn_HOST_TXCSR) Field Descriptions

Bits	Field Name	Description
15	AUTOSET	DMA Mode: The CPU needs to set the AUTOSET bit prior to enabling the Tx DMA. CPU Mode: If the CPU sets the AUTOSET bit, the TXPKTRDY bit will be automatically set when data of the maximum packet size (value in TXMAXP) is loaded into the Tx FIFO. If a packet of less than the maximum packet size is loaded, then the TXPKTRDY bit will have to be set manually.
14	Reserved	Reserved
13	MODE	Set this bit to enable the endpoint direction as Tx, and clear the bit to enable it as Rx. Note: This bit has any effect only where the same endpoint FIFO is used for both Transmit and Receive transactions.
12	DMAEN	Set this bit to enable the DMA request for the Tx endpoint.
11	FRCDATATOG	Set this bit to force the endpoint data toggle to switch and the data packet to be cleared from the FIFO, regardless of whether an ACK was received. This can be used by Interrupt Tx endpoints that are used to communicate rate feedback for Isochronous endpoints.
10	DMAMODE	This bit should always be set to 1 when the DMA is enabled.
9	DATATOGWREN	Write 1 to this bit to enable the DATATOG bit to be written. This bit is automatically cleared once the new value is written to DATATOG.
8	DATATOG	When read, this bit indicates the current state of the Tx EP data toggle. If DATATOGWREN is high, this bit can be written with the required setting of the data toggle. If DATATOGWREN is low, any value written to this bit is ignored.
7	NAK_TIMEOUT	This bit will be set when the Tx endpoint is halted following the receipt of NAK responses for longer than the time set as the NAKLIMIT by the TXINTERVAL register. It should be cleared to allow the endpoint to continue. Note: This is valid only for Bulk endpoints.
6	CLRDATATOG	Write a 1 to this bit to reset the endpoint data toggle to 0.
5	RXSTALL	This bit is set when a STALL handshake is received. The FIFO is flushed and the TXPKTRDY bit is cleared (see below). You should clear this bit.
4	SETUPPKT	Set this bit at the same time as TXPKTRDY is set, to send a SETUP token instead of an OUT token for the transaction. Note: Setting this bit also clears the DATATOG bit.
3	FLUSHFIFO	Write a 1 to this bit to flush the next packet to be transmitted from the endpoint Tx FIFO. The FIFO pointer is reset and the TXPKTRDY bit (below) is cleared. Note: FlushFIFO has no effect unless the TXPKTRDY bit is set. Also note that, if the FIFO is double-buffered, FLUSHFIFO may need to be set twice to completely clear the FIFO.
2	ERROR	The USB controller sets this bit when 3 attempts have been made to send a packet and no handshake packet has been received. You should clear this bit. An interrupt is generated when the bit is set. This is valid only when the endpoint is operating in Bulk or Interrupt mode.
1	FIFONOTEMPTY	The USB controller sets this bit when there is at least 1 packet in the Tx FIFO.
0	TXPKTRDY	Set this bit after loading a data packet into the FIFO. It is cleared automatically when a data packet has been transmitted. An interrupt is generated (if enabled) when the bit is cleared.

15.5.6.2.6 Maximum Packet Size for Peripheral/Host Receive Endpoint Register (USBn_RXMAXP)

The maximum packet size for peripheral/host receive endpoint register (USBn_RXMAXP) defines the maximum amount of data that can be transferred through the selected Rx endpoint in a single operation. There is a RxMaxP register for each Rx endpoint (except Endpoint 0). Endpoint 0 resource is hardened in design and max packet size is set to 64 bytes and no user configuration is required or does not exist.

The maximum packet size for peripheral/host receive endpoint register is shown in Figure 15-163 and described in Table 15-178.

Figure 15-163. Maximum Packet Size for Peripheral/Host Receive Endpoint Register (USBn_RXMAXP)

15 – 11	10 – 0
Reserved	MAXPAYLOAD
R-0h	RW-0-400h

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 15-178. Maximum Packet Size for Peripheral Host Receive Endpoint (USBn_RXMAXP) Field Descriptions

Bit	Field	Description
15-11	Reserved	Reserved
10-0	MAXPAYLOAD	Defines the maximum amount of data that can be transferred through the selected Receive endpoint in a single frame/microframe (high-speed transfers). The value set can be up to 1024 bytes, but is subject to the constraints placed by the USB specification on packet sizes for bulk, interrupt, and isochronous transfers in full-speed and high-speed operations. The value written to this register should match the wMaxPacketSize field of the standard endpoint descriptor for the associated endpoint. A mismatch could cause unexpected results.

Table 15-179. Control Status Register for Peripheral Receive Endpoint (USBn_PERI_RXCSR) Field Descriptions

Bit	Field	Description
15	AUTOCLEAR	DMA Mode: The CPU sets the AUTOCLEAR bit prior to enabling the Rx DMA. CPU Mode: If the CPU sets the AUTOCLEAR bit, then the RXPKTRDY bit will be automatically cleared when a packet of RXMAXP bytes has been unloaded from the Receive FIFO. When packets of less than the maximum packet size are unloaded, RXPKTRDY will have to be cleared manually.
14	ISO	Set this bit to enable the Receive endpoint for Isochronous transfers, and clear it to enable the Receive endpoint for bulk/interrupt transfers.
13	DMAEN	Set this bit to enable the DMA request for the Receive endpoints.
12	DISNYET	DISNYET: Applies only for bulk/interrupt transactions: The CPU sets this bit to disable the sending of NYET handshakes. When set, all successfully received Rx packets are ACK'd including at the point at which the FIFO becomes full. Note: This bit only has any effect in high-speed mode, in which mode it should be set for all Interrupt endpoints. PID_ERROR: Applies only for ISO Transactions: The core sets this bit to indicate a PID error in the received packet.
11	DMAMODE	Always clear this bit to 0.
10	DATATOGWREN	Write 1 to this bit to enable the DATATOG bit to be written. This bit is automatically cleared once the new value is written to DATATOG.
9	DATATOG	When read, this bit indicates the current state of the Receive EP data toggle. If DATATOGWREN is high, this bit can be written with the required setting of the data toggle. If DATATOGWREN is low, any value written to this bit is ignored.
8	Reserved	Reserved
7	CLRDATATOG	Write a 1 to this bit to reset the endpoint data toggle to 0.
6	SENTSTALL	This bit is set when a STALL handshake is transmitted. The FIFO is flushed and the TXPKTRDY bit is cleared. You should clear this bit.
5	SENDSTALL	Write a 1 to this bit to issue a STALL handshake. Clear this bit to terminate the stall condition. Note: This bit has no effect where the endpoint is being used for Isochronous transfers.
4	FLUSHFIFO	Write a 1 to this bit to flush the next packet to be read from the endpoint Receive FIFO. The FIFO pointer is reset and the RXPKTRDY bit is cleared. Note: FLUSHFIFO has no effect unless RXPKTRDY is set. Also note that, if the FIFO is double-buffered, FLUSHFIFO may need to be set twice to completely clear the FIFO.

Bit	Field	Description
15	AUTOCLEAR	DMA Mode: The CPU sets the AUTOCLEAR bit prior to enabling the Rx DMA. CPU Mode: If the CPU sets the AUTOCLEAR bit, then the RXPKTRDY bit will be automatically cleared when a packet of RXMAXP bytes has been unloaded from the Receive FIFO. When packets of less than the maximum packet size are unloaded, RXPKTRDY will have to be cleared manually.
14	AUTOREQ	If the CPU sets the AUTOREQ bit, then the REQPKT bit will be automatically set when the RXPKTRDY bit is cleared. Note: This bit is automatically cleared when a short packet is received.
13	DMAEN	Set this bit to enable the DMA request for the Receive endpoints.
12	DISNYET	Set this bit to disable the sending of NYET handshakes. When set, all successfully received Receive packets are ACKED including at the point at which the FIFO becomes full. Note: This bit only has any effect in high-speed mode, in which mode it should be set for all Interrupt endpoints.
11	DMAMODE	Always clear this bit to 0.
10	DATATOGWREN	Write 1 to this bit to enable the DATATOG bit to be written. This bit is automatically cleared once the new value is written to DATATOG.
9	DATATOG	When read, this bit indicates the current state of the Receive EP data toggle. If DATATOGWREN is high, this bit can be written with the required setting of the data toggle. If DATATOGWREN is low, any value written to this bit is ignored.
8	Reserved	Reserved
7	CLRDATATOG	Write a 1 to this bit to reset the endpoint data toggle to 0.
6	RXSTALL	When a STALL handshake is received, this bit is set and an interrupt is generated. You should clear this bit.
5	REQPKT	Write a 1 to this bit to request an IN transaction. It is cleared when RXPKTRDY is set.
4	FLUSHFIFO	Write a 1 to this bit to flush the next packet to be read from the endpoint Receive FIFO. The FIFO pointer is reset and the RXPKTRDY bit is cleared. Note: FLUSHFIFO has no effect unless RXPKTRDY is set. Also note that, if the FIFO is double-buffered, FLUSHFIFO may need to be set twice to completely clear the FIFO.

Table 15-180. Control Status Register for Host Receive Endpoint (USBn_HOST_RXCSR) Field Descriptions (continued)

Bit	Field	Description
3	DATAERR_NAKTIMEOUT	When operating in ISO mode, this bit is set when RXPKTRDY is set if the data packet has a CRC or bit-stuff error and cleared when RXPKTRDY is cleared. In Bulk mode, this bit will be set when the Receive endpoint is halted following the receipt of NAK responses for longer than the time set as the NAK Limit by the RXINTERVAL register. You should clear this bit to allow the endpoint to continue.
2	ERROR	The USB controller sets this bit when three attempts have been made to receive a packet and no data packet has been received. You should clear this bit. An interrupt is generated when the bit is set. Note: This bit is only valid when the transmit endpoint is operating in Bulk or Interrupt mode. In ISO mode, it always returns zero.
1	FIFOFULL	This bit is set when no more packets can be loaded into the Receive FIFO.
0	RXPKTRDY	This bit is set when a data packet has been received. You should clear this bit when the packet has been unloaded from the Receive FIFO. An interrupt is generated when the bit is set.

15.5.6.2.9 Count 0 Register (USBn_COUNT0)

The count 0 register (USBn_COUNT0) is a 7-bit read-only register that indicates the number of received data bytes in the Endpoint 0 FIFO. The value returned changes as the contents of the FIFO change and is only valid while RxPktRdy (bit 0) is set. This register is shown in Figure 15-166 and described in Table 15-181.

15.5.6.2.10 Receive Count Register (USBn_RXCOUNT)

The receive count register (USBn_RXCOUNT) is a 13-bit read-only register that holds the number of received data bytes in the packet currently in line to be read from the Rx FIFO for endpoints other than endpoint 0.

Note: The value returned changes as the FIFO is unloaded and is only valid while RxPktRdy (bit 0) is set.

The receive count register is shown in Figure 15-167 and described in Table 15-182.

Figure 15-167. Receive Count Register (USBn_RXCOUNT)

15–13	12–0

Bit	Field	Description
15-13	Reserved	Reserved
12-0	EPRXCOUNT	Holds the number of received data bytes in the packet in the Receive FIFO. The value returned changes as the contents of the FIFO change and is only valid while RXPKTRDY of PERI_RXCSR or HOST_RXCSR is set.

15.5.6.2.11 Type Register (Host Mode Only) (USBn_HOST_TYPE0)

The type register (Host mode only) (USBn_HOST_TYPE0) is an 8-bit register, meaningful only when controller assumes the role of a host, of which only bits 6 and 7 are implemented. These bits should be written with the operating speed of the targeted device. This register is shown in Figure 15-168 and described in Table 15-183.

15.5.6.2.12 Transmit Type Register (Host Mode Only) (USBn_HOST_TXTYPE)

The transmit type register (Host mode only) (USBn_HOST_TXTYPE) is an 8-bit register that should be written with the endpoint number to be targeted by the endpoint, the transaction protocol to use for the currently-selected Tx endpoint, and its operating speed. There is a TxType register for each configured Tx endpoint (except Endpoint 0).

The transmit type register is shown in Figure 15-169 and described in Table 15-184.

Figure 15-169. Transmit Type Register (Host Mode Only) (USBn_HOST_TXTYPE)

15.5.6.2.13 NAKLimit0 Register (Host Mode Only) (USBn_HOST_NAKLIMIT0)

The NAKLimit0 register (Host mode only) (USBn_HOST_NAKLIMIT0) is a 5-bit register that sets the number of frames/microframes (high-speed transfers) after which endpoint 0 should timeout on receiving a stream of NAK responses. (Equivalent settings for other endpoints can be made through their TxInterval and RxInterval registers.) The number of frames/microframes selected is 2(m-1) (where m is the value set in the register, valid values 2 – 16). If the host receives NAK responses from the target for more frames than the number represented by the Limit set in this register, the endpoint will be halted. Note: A value of 0 or 1 disables the NAK timeout function.

The NAKLimit0 register is shown in Figure 15-170 and described in Table 15-185.

Figure 15-170. NAKLimit0 Register (Host Mode Only) (USBn_HOST_NAKLIMIT0)

7 – 5	4 – 0
Reserved	EP0NAKLIMIT
R-0h	R/W-0-1Fh

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 15-185. NAKLimit0 Register (Host Mode Only) (USBn_HOST_NAKLIMIT0) Field Descriptions

Bit	Field	Description
7-5	Reserved	Reserved
4-0	EP0NAKLIMIT	Sets the number of frames/microframes (high-speed transfers) after which endpoint 0 should time out on receiving a stream of NAK responses. The number of frames/microframes selected is 2(-1) (where m is the value set in the register, valid values 2-16). If the host receives NAK responses from the target for more frames than the number represented by the Limit set in this register, the endpoint will be halted. Note: A value of 0 or 1 disables the NAK timeout function.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

15.5.6.2.14 Transmit Interval Register (Host Mode Only) (USBn_HOST_TXINTERVAL)

The transmit interval register (Host mode only) (USBn_HOST_TXINTERVAL) is an 8-bit register (meaningful only when controller assumes the role of a host) that, for interrupt and isochronous transfers, defines the polling interval for the currently-selected Tx endpoint. For bulk endpoints, this register sets the number of frames/microframes after which the endpoint should timeout on receiving a stream of NAK responses. There is a TxInterval register for each configured Tx endpoint (except endpoint 0).

The transmit interval register is shown in Figure 15-171 and described in Table 15-186.

Figure 15-171. Transmit Interval Register (Host Mode Only) (USBn_HOST_TXINTERVAL)

7							0
POLINTVL_NAKLIMIT							
R/W-0-FFh							

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 15-186. Transmit Interval Register (Host Mode Only) (USBn_HOST_TXINTERVAL) Field Descriptions

Bit	Field	Description			
7-0	POLINTVL_NAKLIMIT	For interrupt and isochronous transfers, defines the polling interval for the currently-selected transmit endpoint. For bulk endpoints, sets the number of frames/microframes after which the endpoint should timeout on receiving a stream of NAK responses. There is a transmit interval register for each configured transmit endpoint (except endpoint 0). In each case, the value that is set defines a number of frames/microframes (high-speed transfers), as follows:			
		Transfer Type	Speed	Valid values (m)	Interpretation
		Interrupt	Low Speed or Full Speed	1-255	Polling interval is m frames
				1-16	Polling interval is 2(-1) microframes
		Isochronous	Full Speed or High Speed	1-16	Polling interval is 2(-1) frames/microframes
		Bulk	Full Speed or High Speed	2-16	NAK Limit is 2(-1)frames/microframes
		Note: A value of 0 or 1 disables the NAK timeout function.

15.5.6.2.15 Receive Type Register (Host Mode Only) (USBn_HOST_RXTYPE)

The receive type register (Host mode only) (USBn_HOST_RXTYPE) is an 8-bit register that should be written with the endpoint number to be targeted by the endpoint, the transaction protocol to use for the currently-selected Rx endpoint, and its operating speed. There is a RxType register for each configured Rx endpoint (except endpoint 0).

The receive type register is shown in Figure 15-172 and described in Table 15-187.

15.5.6.2.16 Receive Interval Register (Host Mode Only) (USBn_HOST_RXINTERVAL)

The receive interval register (Host mode only) (USBn_HOST_RXINTERVAL) is an 8-bit register (only meaningful in host mode only) that, for Interrupt and Isochronous transfers, defines the polling interval for the currently-selected Rx endpoint. For bulk endpoints, this register sets the number of frames/microframes after which the endpoint should timeout on receiving a stream of NAK responses. There is a RxInterval register for each configured Rx endpoint (except endpoint 0).

The receive interval register is shown in Figure 15-173 and described in Table 15-188.

Figure 15-173. Receive Interval Register (Host Mode Only) (USBn_HOST_RXINTERVAL)

7							0

15.5.6.2.17 Configuration Data Register (USBn_CONFIGDATA)

The configuration data register (USBn_CONFIGDATA) is an 8-bit read-only register that returns information about the selected core configuration. This register information can only be accessed from Indexed Region and INDEX has to be programmed, with zero, selecting endpoint 0. This register is shown in Figure 15-174 and described in Table 15-189.

Figure 15-174. Configuration Data Register (USBn_CONFIGDATA)

15.5.7 FIFOs

This address range provides access to the endpoint FIFOs. Register offset addresses for this block is 20h to 5Fh.

15.5.7.1 Transmit and Receive FIFO Register for Endpoint 0 - 15 (USBn_FIFO0 – USBn_FIFO15)

This address range provides 16 addresses for CPU access to the FIFOs for each endpoint. Writing to these addresses loads data into the TxFIFO for the corresponding endpoint. Reading from these addresses unloads data from the RxFIFO for the corresponding endpoint. The address range is 20h – 5Fh and the FIFOs are located on 32-bit double-word boundaries (endpoint 0 at 20h, endpoint 1 at 24h ... Endpoint 15 at 5Ch).

Note 1: Transfers to and from FIFOs may be 8-bit, 16-bit or 32-bit as required, and any combination of access is allowed provided the data accessed is contiguous. However, all the transfers associated with one packet must be of the same width so that the data is consistently byte-, word- or double-word-aligned. The last transfer may however contain fewer bytes than the previous transfers in order to complete an odd-byte or odd-word transfer.

Note 2: Depending on the size of the FIFO and the expected maximum packet size, the FIFOs support either single-packet or doublepacket buffering. However, burst writing of multiple packets is not supported as flags need to be set after each packet is written.

Note 3: Following a STALL response or a Tx strike out error on dndpoint 1 – 15, the associated FIFO is completely flushed.

The transmit and receive FIFO register for endpoint 0 - 15 (USBn_FIFO0 – USBn_FIFO15) is shown in Figure 15-175 and described in Table 15-190.

64h	Transmit Endpoint FIFO Address Register
66h	Receive Endpoint FIFO Address Register
6Ch	Hardware Version Register

15.5.7.2.1 Device Control Register (USBn_DEVCTL)

The device control register (USBn_DEVCTL) is an 8-bit register that is used to select whether the USB controller is operating in peripheral mode or in host mode, and for controlling and monitoring the USB VBus line. If the PHY is suspended no PHY clock is received and the VBus is not sampled. This register is shown in Figure 15-176 and described in Table 15-192.

Figure 15-176. Device Control Register (USBn_DEVCTL)

7	6	5	4	3	2	1	0
BDEVICE	FSDEV	LSDEV	VBUS		HOSTMODE	HOSTREQ	SESSION

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 15-192. Device Control Register (USBn_DEVCTL) Field Descriptions

Bit	Field	Value	Description
7	BDEVICE		This read-only bit indicates whether the USB controller is operating as the 'A' device or the 'B' device.
		0	A device
		1	B device
6	FSDEV		This read-only bit is set when a full-speed or high-speed device has been detected being connected to the port (high-speed devices are distinguished from full-speed by checking for high-speed chirps when the device is reset). Only valid in Host mode.
5	LSDEV		This read-only bit is set when a low-speed device has been detected being connected to the port. Only valid in Host mode.
4-3	VBUS		These read-only bits encode the current VBus level as follows:
		0h	Below session end
		1h	Above session dnd, below AValid
		2h	Above AValid, below VBusValid
		3h	Above VBusValid
2	HOSTMODE		This read-only bit is set when the USB controller is acting as a Host.
1	HOSTREQ		When set, the USB controller initiates the Host negotiation when suspend mode is entered. It is cleared when Host negotiation is completed. ('B' device only)
0	SESSION		When operating as an 'A' device, you must set or clear this bit start or end a session. When operating as a 'B' device, this bit is set/cleared by the USB controller when a session starts/ends. You must also set this bit to initiate the session request protocol. When the USB controller is in suspend mode, you may clear the bit to perform a software disconnect. A special software routine is required to perform SRP. Details will be made available in a later document version.

15.5.7.2.2 Transmit Endpoint FIFO Size Register (USBn_TXFIFOSZ)

The allocation of FIFO space to the different endpoints requires the specification for each Tx endpoint:

- The start address of the FIFO within the RAM block
- The maximum size of packet to be supported
- Whether double-buffering is required

The transmit endpoint FIFO size register (USBn_TXFIFOSZ) defines the amount of space that needs to be allocated to the FIFO in either single or double buffering context.

For more information, see the *Dynamic FIFO Allocation* section.

The transmit endpoint FIFO size register is shown in Figure 15-177 and described in Table 15-193.

Figure 15-177. Transmit Endpoint FIFO Size Register (USBn_TXFIFOSZ)

7	6	5	4	3	0
Reserved			DPB	SZ	
R-0h			R-0-1h	R-0-Fh	

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 15-193. Transmit Endpoint FIFO Size Register (USBn_TXFIFOSZ) Field Descriptions

Bit	Field	Value	Description
7-5	Reserved		Reserved
4	DPB		Double packet buffering enable.
		0	Single packet buffering is supported.
		1	Double packet buffering is enabled
3-0	SZ		Maximum packet size to be allowed (before any splitting within the FIFO of Bulk packets prior to transmission). If m = SZ, the FIFO size is calculated as 2(m+3) for single packet buffering and 2(m+4) for dual packet buffering.

15.5.7.2.3 Receive Endpoint FIFO Size Register (USBn_RXFIFOSZ)

The allocation of FIFO space to the different endpoints requires the specification for each Rx endpoint

- The start address of the FIFO within the RAM block
- The maximum size of packet to be supported
- Whether double-buffering is required

The receive endpoint FIFO size register (USBn_RXFIFOSZ) defines the amount of space that needs to be allocated to the FIFO in either single or double buffering context.

For more information, see the *Dynamic FIFO Allocation* section.

The receive endpoint FIFO size register is shown in Figure 15-178 and described in Table 15-194.

Figure 15-178. Receive Endpoint FIFO Size Register (USBn_RXFIFOSZ)

7	6	5	4	3	0
Reserved			DPB	SZ	
0h			0-1h	0-Fh	

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 15-194. Receive Endpoint FIFO Size Register (USBn_RXFIFOSZ) Field Descriptions

Bit	Field	Value	Description
7-5	Reserved		Reserved
4	DPB		Double packet buffering enable.
		0	Single packet buffering is supported.
		1	Double packet buffering is enabled
3-0	SZ		Maximum packet size to be allowed (before any splitting within the FIFO of Bulk packets prior to transmission). If m = SZ, the FIFO size is calculated as 2(m+3) for single packet buffering and 2(m+4) for dual packet buffering.

15.5.7.2.4 Transmit Endpoint FIFO Address Register (USBn_TXFIFOADDR)

The allocation of FIFO space to the different endpoints requires the specification for each Tx endpoint:

- The start address of the FIFO within the RAM block
- The maximum size of packet to be supported
- Whether double-buffering is required

The transmit endpoint FIFO address register (USBn_TXFIFOADDR) the coding for the start address of the FIFO. Note that the 1st 64 bytes of the FIFO RAM is reserved for the use of endpoint 0. Allocation of FIFO should exclude this reserved location.

The transmit endpoint FIFO address register is shown in Figure 15-179 and described in Table 15-195.

12-0	ADDR	Start address of endpoint FIFO in units of 8 bytes If m = ADDR, then the start address is 8 × m

15.5.7.2.6 Hardware Version Register (USBn_HWVERS)

The hardware version register (USBn_HWVERS) is a 16-bit read-only register that returns information about the version of the RTL from which the core hardware was generated, in particular the RTL version number (REVMAJ.REVMIN). This register is shown in Figure 15-181 and described in Table 15-197.

Figure 15-181. Hardware Version Register (USBn_HWVERS)

84h	Receive Function Address Register
86h	Receive Hub Address Register
87h	Receive Hub Port Register

15.5.7.3.1 Transmit Function Address Register (USBn_TXFUNCADDRm)

The transmit function address register (USBn_TXFUNCADDRm) is a 7-bit read/write register (meaningful in host mode operation only) that records the address of the target function that is to be accessed through the associated endpoint (EPn). USBn_ TXFUNCADDR needs to be defined for each Tx endpoint that is used.

Note: USBn_TXFUNCADDRm needs to be defined for endpoint 0. This register, together with the USBn_TXHUBADDRm and USBn_TXHUBPORTm registers described below, allow the allocation of multiple devices to the USB controller endpoints.

The transmit function address register is shown in Figure 15-182 and described in Table 15-199.

15.5.7.3.2 Transmit Hub Address Register (USBn_TXHUBADDRm)

The transmit hub address register (USBn_TXHUBADDRm) is an 8-bit read/write register which, like USBn_TXHUBPORTm, only need to be written where a full- or low-speed device is connected to Tx endpoint EPn via a high-speed USB 2.0 hub that carries out the necessary transaction translation to convert between high-speed transmission and full-/low-speed transmission. In such circumstances:

- The lower 7 bits should record the address of this USB 2.0 hub
- The top bit should record whether the hub has multiple transaction translators (set to ‘0’ if single transaction translator; set to ‘1’ if multiple transaction translators).

Note: If endpoint 0 is connected to a hub, then USBn_TXHUBADDRm need to be defined for this endpoint.

The transmit hub address register is shown in Figure 15-183 and described in Table 15-200.

Figure 15-183. Transmit Hub Address Register (USBn_TXHUBADDRm)

7	6 … 0
Reserved	FUNCADDR
0h	0-7Fh

Bit	Field	Description
7	MULT_TRANS	Set to 1 if hub has multiple transaction translators. Cleared to 0 if only single transaction translator is available.
6-0	HUBADDR	Address of hub

15.5.7.3.3 Transmit Hub Port Register (USBn_TXHUBPORTm)

The transmit hub port register (USBn_TXHUBPORTm) (meaningful in host mode operation only) only needs to be written where a full- or low-speed device is connected to Tx Endpoint EPn via a high-speed USB 2.0 hub which carries out the necessary transaction translation. In such circumstances, these 7-bit read/write registers need to be used to record the port of that USB 2.0 hub through which the target associated with the endpoint is accessed.

Note: If Endpoint 0 is connected to a hub, then USBn_TXHUBPORT needs to be defined for this endpoint.

The transmit hub port register is shown in Figure 15-184 and described in Table 15-201.

Figure 15-184. Transmit Hub Port Register (USBn_TXHUBPORTm)

15.5.7.3.4 Receive Function Address Register (USBn_RXFUNCADDRm)

The receive function address register (USBn_RXFUNCADDRm) is a 7-bit read/write register (meaningful in host mode operation only) that record the address of the target function that is to be accessed through the associated endpoint (EPn). USBn_ RXFUNCADDR needs to be defined for each Rx endpoint that is used.

Note: USBn_RXFUNCADDRm need to be defined for Endpoint 0. This register (together with the USBn_RXHUBADDRm and USBn_RXHUBPORTm registers described below) allow the allocation of multiple devices to the USB controller endpoints.

The receive function address register is shown in Figure 15-185 and described in Table 15-202.

Figure 15-185. Receive Function Address Register (USBn_RXFUNCADDRm)

15.5.7.4 Non-Indexed Endpoint Control/Status Registers

The registers available at indexed region, offset 10h–1Fh, are accessible independently of the setting of the Index register. The Non-Indexed region has dedicated block of register space for each endpoint with memory block between 100h–10Fh are reserved for endpoint 0 registers; memory block between 110h–11Fh are reserved for endpoint 1 registers; memory block between 120h–12Fh are reserved for endpoint 2 registers; and so on.

Table 15-205 and Table 15-206 display the set of endpoint registers that are accessible from their dedicated block of memory in both peripheral and host mode, respectively. Note that the definitions of these register is discussed in detail in Section 15.5.6.2.

Table 15-205. Peripheral Mode Configuration and Status Register Mapping where n=0,1 (USB0 or USB1) and m=1-15 (endpoint number)

Offset	Name	Description (within Indexed Region)

16.1 Mailbox

16.1.1 Introduction

16.1.1.1 Features

Global features of the Mailbox module are:

- OCP slave interface (L4) supports:
  - 32-bit data bus width
  - 8/16/32 bit access supported
  - 9-bit address bus width
  - Burst not supported
- 8 mailbox sub-modules
- Each mailbox sub module allows 1-way communication between 2 initiators
- Flexible mailbox/initiators assignment scheme
- 4 messages per mailbox sub-module
- 32-bit message width
- Support of 16/32-bit addressing scheme
- Non-intrusive emulation
- 4 interrupts (one per user: 1 to MPU Subsystem, 2 to PRUSS, and 1 to WakeM3)

16.1.1.2 Unsupported Features

There are no unsupported features for Mailbox on this device.

DRAFT ONLY

16.1.2 Integration

This device contains a single instantiation of the Mailbox module at the system level. The mailbox function is made of eight sub-module mailboxes each supporting a 1-way communication between two initiators. The communication protocol from the sender to the receiver is implemented with mailbox registers using interrupts. The sender sends information to the receiver by writing to the mailbox. Interrupt signaling is used to notify the receiver a message has been queued or the sender for overflow situation.

The eight mailboxes are enough to handle communications between the MPU Subsystem, PRUSS PRUs, and WakeM3. Note that because the WakeM3 has access only to L4_Wakeup peripherals it does not have access to the Mailbox registers. A mailbox interrupt can still be sent to the M3 to trigger message notification. The actual message payload must be placed in either M3 internal memory or in the Control Module Interprocessor Message registers (IPC_MSG_REG{0-7}).

16.1.2.1 Mailbox Connectivity Attributes

The general connectivity for the Mailbox is shown in Table 16-1.

Table 16-1. Mailbox Connectivity Attributes

Attributes	Type
Power Domain	Peripheral Domain
Clock Domain	L4PER_L4LS_GCLK
Reset Signals	PER_DOM_RST_N
Idle/Wakeup Signals	Smart Idle
Interrupt Requests	4 Interrupts mail_u0 – to MPU Subsystem mail_u1 – to PRUSS (PRU0) mail_u2 – to PRUSS (PRU1) mail_u3 – to WakeM3
DMA Requests	None
Physical Address	L4 Peripheral slave port

16.1.2.2 Mailbox Clock and Reset Management

The mailbox function operates from the L4 interface clock.

Table 16-2. Mailbox Clock Signals

Clock Signal	Max Freq	Reference / Source	Comments
Functional / Interface clock	100 MHz	CORE_CLKOUTM4 / 2	pd_per_l4ls_gclk From PRCM

16.1.2.3 Mailbox Pin List

The Mailbox module does not include any external interface pins.

16.2 Spinlock

16.2.1 Introduction

16.2.2 SPINLOCK Registers

Table 16-3 lists the memory-mapped registers for the SPINLOCK. See your device-specific data manual for the memory address of these registers. All other register offset addresses not listed in Table 16-3 should be considered as reserved locations and the register contents should not be modified.

Table 16-3. SPINLOCK REGISTERS

Offset	Acronym	Register Description	Section
0h	REV	Read-only IP revision identifier (X.Y.R) used by software to determine features, bugs and compatibility of an instance of this the Spin Lock module.	Section 16.2.2.1
10h	SYSCONFIG	This register controls the various parameters of the OCP interface. Note that several fields are present by read-only.	Section 16.2.2.2
14h	SYSTATUS	This register provides status information about this instance of the Spin Lock module.	Section 16.2.2.3
800h	LOCK_REG_0	This register is read when attempting to acquire a lock. The lock is automatically taken if it was not taken and the value returned by the read is zero. If the lock was already taken, then the read returns one. Writing a zero to this register frees the lock.	Section 16.2.2.4
804h	LOCK_REG_1	This register is read when attempting to acquire a lock. The lock is automatically taken if it was not taken and the value returned by the read is zero. If the lock was already taken, then the read returns one. Writing a zero to this register frees the lock.	Section 16.2.2.5
808h	LOCK_REG_2	This register is read when attempting to acquire a lock. The lock is automatically taken if it was not taken and the value returned by the read is zero. If the lock was already taken, then the read returns one. Writing a zero to this register frees the lock.	Section 16.2.2.6
80Ch	LOCK_REG_3	This register is read when attempting to acquire a lock. The lock is automatically taken if it was not taken and the value returned by the read is zero. If the lock was already taken, then the read returns one. Writing a zero to this register frees the lock.	Section 16.2.2.7
810h	LOCK_REG_4	This register is read when attempting to acquire a lock. The lock is automatically taken if it was not taken and the value returned by the read is zero. If the lock was already taken, then the read returns one. Writing a zero to this register frees the lock.	Section 16.2.2.8
814h	LOCK_REG_5	This register is read when attempting to acquire a lock. The lock is automatically taken if it was not taken and the value returned by the read is zero. If the lock was already taken, then the read returns one. Writing a zero to this register frees the lock.	Section 16.2.2.9
818h	LOCK_REG_6	This register is read when attempting to acquire a lock. The lock is automatically taken if it was not taken and the value returned by the read is zero. If the lock was already taken, then the read returns one. Writing a zero to this register frees the lock.	Section 16.2.2.10
81Ch	LOCK_REG_7	This register is read when attempting to acquire a lock. The lock is automatically taken if it was not taken and the value returned by the read is zero. If the lock was already taken, then the read returns one. Writing a zero to this register frees the lock.	Section 16.2.2.11

16.2.2.10 LOCK_REG_6 Register (offset = 818h) [reset = 0h]

This register is read when attempting to acquire a lock. The lock is automatically taken if it was not taken and the value returned by the read is zero. If the lock was already taken, then the read returns one. Writing a zero to this register frees the lock.

LOCK_REG_6 is shown in Figure 16-10 and described in Table 16-13.

16.2.2.28 LOCK_REG_24 Register (offset = 860h) [reset = 0h]

This register is read when attempting to acquire a lock. The lock is automatically taken if it was not taken and the value returned by the read is zero. If the lock was already taken, then the read returns one. Writing a zero to this register frees the lock.

LOCK_REG_24 is shown in Figure 16-28 and described in Table 16-31.

17.1 Introduction

17.1.1 MMCHS Features

The general features of the MMCHS host controller IP are:

- Built-in 1024-byte buffer for read or write
- Two DMA channels, one interrupt line
- Clock support
  - 96-MHz functional clock source input
  - up to 384Mbit/sec (48MByte/sec) in MMC mode 8-bit data transfer
  - up to 192Mbit/sec (24MByte/sec) in High-Speed SD mode 4-bit data transfer
  - up to 24Mbit/sec (3MByte/sec) in Default SD mode 1-bit data transfer
- Support for SDA 3.0 Part A2 programming model
- Serial link supports full compliance with:
  - MMC command/response sets as defined in the MMC standard specification v4.3.
  - SD command/response sets as defined in the SD Physical Layer specification v3.00
  - SDIO command/response sets and interrupt/read-wait suspend-resume operations as defined in the SD part E1 specification v 2 .00
  - SD Host Controller Standard Specification sets as defined in the SD card specification Part A2 v2.00

17.1.2 Unsupported MMCHS Features

The MMCHS module features not supported in this device are shown in Table 17-1.

Table 17-1. Unsupported MMCHS Features

Feature	Reason
MMC Out-of-band interrupts	MMC_OBI input tied low
Master DMA operation	Disabled through synthesis parameter
Card Supply Control (MMCHS(1-2))	Signal not pinned out

17.2 Integration

This device contains three instances of the Multimedia Card (MMC), Secure Digital (SD), and Secure Digital I/O (SDIO) high speed interface module (MMCHS). The controller provides an interface to an MMC, SD memory card or SDIO card.

The application interface is responsible for managing transaction semantics; the MMC/SDIO host controller deals with MMC/SDIO protocol at transmission level, packing data, adding CRC, start/end bit and checking for syntactical correctness. Figure 17-1 through Figure 17-3 below show examples of systems using the MMCHS controller. Note that the power switch control is only available on the MMCHS0 interface.

Figure 17-1. MMCHS Module SDIO Application

Figure 17-2. MMCHS SD (4-bit) Card Application

Figure 17-3. MMCHS Module MMC Application

17.2.1 MMCHS Connectivity Attributes

The general connectivity attributes for the three MMCHS modules are shown in Table 17-2.

Table 17-2. MMCHS Connectivity Attributes

Attributes	Type
Power Domain	Peripheral Domain
Clock Domain	PD_PER_L4LS_GCLK (OCP) PD_PER_MMC_FCLK (Func) CLK_32KHZ (Debounce)
Reset Signals	PER_DOM_RST_N
Idle/Wakeup Signals	Smart Idle
Interrupt Requests	1 interrupt to Sabertooth
DMA Requests	2 DMA requests to EDMA (Active low, need to be inverted in glue logic)
Physical Address	L4 Peripheral slave port

17.2.2 MMCHS Clock and Reset Management

The MMCHS controller has separate bus interface and functional clocks. The debounce clock is created by dividing the 48-MHz (24 MHz @ OPP 50) clock in the PRCM by 2 and then dividing the resulting 24-MHz (12 MHz @ OPP50) clock by a fixed 732.4219 (366.2109 @ OPP 50) in the Control Module to get a 32-KHz clock. This clock is fed back into the PRCM for clock gating. (See the CLK32KDIVRATIO_CTRL register in Ch 5 for more details).

Table 17-3. MMCHS Clock Signals

Clock Signal	Max Freq	Reference / Source	Comments
CLK Interface clock	100 MHz	CORE_CLKOUTM4 / 2	pd_per_l4ls_gclk from PRCM
CLKADPI Functional clock	48 MHz	PER_CLKOUTM2 / 4	pd_per_mmc_fclk from PRCM
CLK32 Input de-bounce clock	32.768 KHz	CLK_24 / 732.4219	clk_32KHz from PRCM

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

17.2.3 MMCHS Pin List

The MMCHS interface pins are summarized in Table 17-4.

Table 17-4. MMCHS Pin List

Pin	Type	Description
MMC*x*_CLK	I/O	MMC/SD serial clock output
MMC*x*_CMD	I/O	MMC/SD command signal
MMC*x*_DAT0	I/O	MMC/SD data signal
MMC*x*_DAT1	I/O	MMC/SD data signal, SDIO interrupt input
MMC*x*_DAT2	I/O	MMC/SD data signal, SDIO read wait output
MMC*x*_DAT[7:3]	I/O	MMC/SD data signals
MMC*x*_POW	O	MMC/SD power supply control (MMCHS 0 only)
MMC*x*_SDCD	I	SD card detect (from connector)
MMC*x*_SDWP	I	SD write protect (from connector)
MMC*x*_OBI	I	MMC out of band interrupt

The direction of the data lines depends on the selected data transfer mode as summarized in Table 17-5.

Table 17-5. DAT Line Direction for Data Transfer Modes

	MMC/SD 1-bit mode	MMC/SD 4-bit mode	MMC/SD 8-bit mode	SDIO 1-bit mode	SDIO 4-bit mode
DAT[0]	I/O	I/O	I/O	I/O	I/O
DAT[1]	I[(1)]	I/O	I/O	I[(2)]	I/O or I[(2)]
DAT[2]	I[(1)]	I/O	I/O	I/O[(3)]	I/O or O[(3)]
DAT[3]	I[(1)]	I/O	I/O	I[(1)]	I/O
DAT[4]	I[(1)]	I[(1)]	I/O	I[(1)]	I[(1)]
DAT[5]	I[(1)]	I[(1)]	I/O	I[(1)]	I[(1)]
DAT[6]	I[(1)]	I[(1)]	I/O	I[(1)]	I[(1)]
DAT[7]	I[(1)]	I[(1)]	I/O	I[(1)]	I[(1)]

(1) Hi-Z state to avoid bus conflict.
(2) To support incoming interrupt from the SDIO card.
(3) To support read wait to the SDIO card. By default it is Input, Output only in read wait period.

The direction of the MMCHS data buffers are controlled by ADPDATDIROQ signals. ADPDATDIROQ[i] = 1 sets the corresponding DAT signal(s) in read position (input) and ADPDATDIROQ[i] = 0 sets the corresponding DAT signal(s) in write position (output). Additionally, the ADPDATDIRLS signals are provided (with opposite polarity) to control the direction of external level shifters. The value of these control signals for the various data modes are summarized in Table 17-6.

Table 17-6. ADPDATDIROQ and ADPDATDIRLS Signal States

	MMC/SD 1-bit mode	MMC/SD 4-bit mode	MMC/SD 8-bit mode	SDIO 1-bit mode	SDIO 4-bit mode
DAT[0]	ADPDATDIRLS[0] = 0 / 1 ADPDATDIROQ[0] = 1 / 0	ADPDATDIRLS[0] = 0 / 1 ADPDATDIROQ[0] = 1 / 0	ADPDATDIRLS[0] = 0 / 1 ADPDATDIROQ[0] = 1 / 0	ADPDATDIRLS[0] = 0 / 1	ADPDATDIRLS[0] = 0 / 1 ADPDATDIROQ[0] = 1 / 0
DAT[2]	ADPDATDIRLS[2] = 0 ADPDATDIROQ[2] = 1	ADPDATDIRLS[2] = 0 / 1 ADPDATDIROQ[2] = 1 / 0	ADPDATDIRLS[2] = 0 / 1 ADPDATDIROQ[2] = 1 / 0	ADPDATDIRLS[2] = 0 / 1 ADPDATDIROQ[2] = 1 / 0	ADPDATDIRLS[2] = 0 / 1 ADPDATDIROQ[2] = 1 / 0

17.3 Functional Description

One MMC/SD/SDIO host controller can support one MMC memory card, one SD card, or one SDIO card.

Other combinations (for example, two SD cards, one MMC card, and one SD card) are not supported through a single controller.

17.3.1 MMC/SD/SDIO Functional Modes

17.3.1.1 MMC/SD/SDIO Connected to an MMC, an SD Card, or an SDIO Card

Figure 17-4 shows the MMC/SD/SDIO0 and MMC/SD/SDIO2 host controllers connected to an MMC, an SD, or an SDIO card and its related external connections.

Figure 17-4. MMC/SD 0/2 Connectivity to an MMC/SD Card

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

The following MMC/SD/SDIO controller pins are used

- **MMC_CMD** This pin is used for two-way communication between the connected card and the MMC/SD/SDIO controller. The MMC/SD/SDIO controller transmits commands to the card and the memory card drives responses to the commands on this pin.
- **MMC_DAT7-0** Depending on which type of card you are using, you may need to connect 1, 4, or 8 data lines. The number of DAT pins (the data bus width) is set by the Data Transfer Width (DTW) bit in the MMC control register (SD_HCTL). For more information, see the registers section of this document.
- **MMC_CLK** This pin provides the clock to the memory card from the MMC/SD controller.

  Note: The MMC_CLK pin functions as an output but must be configured as an I/O to internally loopback the clock to time the inputs.

Table 17-7 provides a summary of these pins.

Table 17-7. MMC/SD/SDIO Controller Pins and Descriptions

Pin	Type	1-Bit Mode	4-Bit Mode	8-Bit Mode	Reset Value
MMC_CLK[(1)]	O	Clock Line	Clock Line	Clock Line	High impedance
MMC_CMD	I/O	Command Line	Command Line	Command Line	High impedance
MMC_DAT0	I/O	Data Line 0	Data Line 0	Data Line 0	0
MMC_DAT1	I/O	(not used)	Data Line 1	Data Line 1	0
MMC_DAT2	I/O	(not used)	Data Line 2	Data Line 2	0
MMC_DAT3	I/O	(not used)	Data Line 3	Data Line 3	0
MMC_DAT4	I/O	(not used)	(not used)	Data Line 4	0
MMC_DAT5	I/O	(not used)	(not used)	Data Line 5	0
MMC_DAT6	I/O	(not used)	(not used)	Data Line 6	0
MMC_DAT7	I/O	(not used)	(not used)	Data Line 7	0

(1) The MMC_CLK pin functions as an output but must be configured as an I/O to internally loopback the clock to time the inputs.

Figure 17-5 shows the MMC/SD/SDIO1 host controller connected to an MMC, SD, or SDIO card and its related external connections. Note that MMC/SD/SDIO1 uses the same signals as MMC/SD/SDIO 0 and 2, but adds three additional signals. These are described below.

Figure 17-5. MMC/SD 1 Connectivity to an MMC/SD Card

Copyright © 2011, Texas Instruments Incorporated

The following MMC/SD/SDIO controller pins are used

- **MMC_POW** Used for MMC/SD card's cards on/off power supply control. When high, denotes power-on condition.
- **MMC_SDCD** This input pin serves as the MMC/SD/SDIO carrier detect. This signal is received from a mechanical switch on the slot.
- **MMC_SDWP** This input pin is used for the SD/SDIO card's write protect. This signal is received from a mechanical protect switch on the slot (system dependant). Applicable only for SD and SDIO cards that have a mechanical sliding tablet on the side of the card.

17.3.1.2 Protocol and Data Format

The bus protocol between the MMC/SD/SDIO host controller and the card is message-based. Each message is represented by one of the following parts:

Command: A command starts an operation. The command is transferred serially from the \MMC/SD/SDIO host controller to the card on the mmc_cmd line.

Response: A response is an answer to a command. The response is sent from the card to the MMC/SD/SDIO host controller. It is transferred serially on the mmc_cmd line.

Data: Data are transferred from the MMC/SD/SDIO host controller to the card or from a card to the MMC/SD/SDIO host controller using the DATA lines.

Busy: The mmc_dat0 signal is maintained low by the card as far as it is programming the data received.

CRC status: CRC result is sent by the card through the mmc_dat0 line when executing a write transfer. In the case of transmission error, occurring on any of the active data lines, the card sends a negative CRC status on mmc_dat0. In the case of successful transmission, over all active data lines, the card sends a positive CRC status on mmc_dat0 and starts the data programming procedure.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

17.3.1.2.1 Protocol

There are two types of data transfer:

- Sequential operation
- Block-oriented operation

There are specific commands for each type of operation (sequential or block-oriented). See the *Multimedia Card System Specification*, the *SD Memory Card Specifications*, and the *SDIO Card Specification, Part E1* for details about commands and programming sequences supported by the MMC, SD, and SDIO cards.

> **CAUTION**
>
> Stream commands are supported only by MMC cards.

Figure 17-6 and Figure 17-7 show how sequential operations are defined. Sequential operation is only for 1-bit transfer and initiates a continuous data stream. The transfer terminates when a stop command follows on the mmc_cmd line.

Figure 17-6. Sequential Read Operation (MMC Cards Only)

Figure 17-7. Sequential Write Operation (MMC Cards Only)

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Figure 17-8 and Figure 17-9 show how multiple block-oriented operations are defined. A multiple block-oriented operation sends a data block plus CRC bits. The transfer terminates when a stop command follows on the mmc_cmd line. These operations are available for all kinds of cards.

Figure 17-8. Multiple Block Read Operation (MMC Cards Only)

Figure 17-9. Multiple Block Write Operation (MMC Cards Only)

NOTE:

1. The card busy signal is not always generated by the card; the previous examples show a particular case.
2. It is the software's responsibility to do a software reset after a data timeout to ensure that mmc_clk is stopped. The software reset is done by setting bit 26 in the SD_SYSCTL register to 1.
3. For multiblock transfer, and especially for MMC cards, you can abort a transfer without using a stop command. Use a CMD23 before a data transfer to define the number of blocks that will be transferred, then the transfer stops automatically after the last block (provided the MMC card supports this feature).

17.3.1.2.2 Data Format

Coding Scheme for Command Token

Command packets always start with 0 and end with 1. The second bit is a transmitter bit1 for a host command. The content is the command index (coded by 6 bits) and an argument (for example, an address), coded by 32 bits. The content is protected by 7-bit CRC checksum (see Figure 17-10).

Figure 17-10. Command Token Format

Coding Scheme for Response Token

Response packets always start with 0 and end with a 1. The second bit is a transmitter bit0 for a card response. The content is different for each type of response (R1, R2, R3, R4, R5, and R6) and the content is protected by 7-bit CRC checksum. Depending on the type of commands sent to the card, the SD_CMD register must be configured differently to avoid false CRC or index errors to be flagged on command response (see Table 17-8). For more details about response types, see the *Multimedia Card System Specification*, the *SD Memory Card Specification*, or the *SDIO Card Specification*.

Table 17-8. Response Type Summary[(1)]

Response Type SD_CMD[17:16] RSP_TYPE	Index Check Enable SD_CMD[20] CICE	CRC Check Enable SD_CMD[19] CCCE	Name of Response Type
00	0	0	No Response
01	0	1	R2
10	0	0	R3 (R4 for SD cards)
10	1	1	R1, R6, R5 (R7 for SD cards)
11	1	1	R1b, R5b

(1) The MMC/SD/SDIO host controller assumes that both clocks may be switched off, whatever the value set in the SD_SYSCONFIG[9:8] CLOCKACTIVITY bit.

Figure 17-11 and Figure 17-12 depict the 48-bit and 136-bit response packets.

17.3.2 Resets

17.3.2.1 Hardware Reset

The module is reinitialized by the hardware.

The SD_SYSSTATUS[0] RESETDONE bit can be monitored by the software to check if the module is ready-to-use after a hardware reset.

This hardware reset signal has a global reset action on the module. All configuration registers and all state machines are reset in all clock domains.

This hardware reset signal has a global reset action on the module. All configuration registers and all state-machines are reset in all clock domains.

17.3.2.2 Software Reset

The module is reinitialized by software through the SD_SYSCONFIG[1] SOFTRESET bit. This bit has the same action on the module logic as the hardware signal except for:

- Debounce logic
- SD_PSTATE, SD_CAPA, and SD_CUR_CAPA registers (see corresponding register descriptions)

The SOFTRESET bit is active high. The bit is automatically reinitialized to 0 by the hardware. The SD_SYSCTL[24] SRA bit has the same action as the SOFTRESET bit on the design.

The SD_SYSSTATUS[0] RESETDONE bit can be monitored by the software to check if the module is ready-to-use after a software reset.

Copyright © 2011, Texas Instruments Incorporated

Moreover, two partial software reset bits are provided:

- SD_SYSCTL[26] SRD bit
- SD_SYSCTL[25] SRC bit

These two reset bits are useful to reinitialize data or command processes respectively in case of line conflict. When set to 1, a reset process is automatically released when the reset completes:

- The SD_SYSCTL[26] SRD bit resets all finite state-machines and status management that handle data transfers on both the interface and functional side.
- The SD_SYSCTL[25] SRC bit resets all finite state-machines and status management that handle command transfers on both the interface and functional side.

NOTE: If **any** of the clock inputs are not present for the MMC/SD/SDIO peripheral, the software reset will not complete.

17.3.3 Power Management

The MMC/SD/SDIO host controller can enter into different modes and save power:

- Normal mode
- Idle mode

The two modes are mutually exclusive (the module can be in normal mode or in idle mode). The MMC/SD/SDIO host controller is compliant with the PRCM module handshake protocol. When the MMC/SD/SDIO power domain is off, the only way to wake up the power domain and different MMC/SD/SDIO clocks is to monitor the mmc_dat1 input pin state via a different GPIO line for each MMC/SD/SDIO interface.

17.3.3.1 Normal Mode

The autogating of interface and functional clocks occurs when the following conditions are met:

- The SD_SYSCONFIG[0] AUTOIDLE bit is set to 1.
- There is no transaction on the MMC interface.

The autogating of interface and functional clocks stops when the following conditions are met:

- A register access occurs through the L3 (or L4) interconnect.
- A wake-up event occurs (an interrupt from a SDIO card).
- A transaction on the MMC/SD/SDIO interface starts.

Then the MMC/SD/SDIO host controller enters in low-power state even if SD_SYSCONFIG[0] AUTOIDLE is cleared to 0. The functional clock is internally switched off and only interconnect read and write accesses are allowed.

17.3.3.2 Idle Mode

The clocks provided to MMC/SD/SDIO are switched off upon a PRCM module request. They are switched back upon module request. The MMC/SD/SDIO host controller complies with the PRCM module handshaking protocol:

- Idle request from the system power manager
- Idle acknowledgment from the MMC/SD/SDIO host controller
- Wake-up request from the MMC/SD/SDIO host controller

The idle acknowledgment varies according to the SD_SYSCONFIG[4:3] SIDLEMODE bit field:

- 0: Force-idle mode. The MMC/SD/SDIO host controller acknowledges the system power manager request unconditionally.
- 1h: No-idle mode. The MMC/SD/SDIO host controller ignores the system power manager request and behaves normally as if the request was not asserted.
- 2h: Smart-idle mode. The MMC/SD/SDIO host controller acknowledges the system power manager

Copyright © 2011, Texas Instruments Incorporated

request according to its internal state.

- 3h: Smart-idle wake-up-capable mode. The MMC/SD/SDIO host controller acknowledges the system power manager request according to its internal state. However, the module may generate wake-up events when in idle state (related to IRQ or DMA requests)

During the smart-idle mode period, the MMC/SD/SDIO host controller acknowledges that the OCP and Functional clocks may be switched off whatever the value set in the SD_SYSCONFIG[9:8] CLOCKACTIVITY field.

17.3.3.3 Transition from Normal Mode to Smart-Idle Mode

Smart-idle mode is enabled when the SD_SYSCONFIG[4:3] SIDLEMODE bit field is set to 2h or 3h. The MMC/SD/SDIO host controller goes into idle mode when the PRCM issues an idle request, according to its internal activity. The MMC/SD/SDIO host controller acknowledges the idle request from the PRCM after ensuring the following:

- The current multi/single-block transfer is completed.
- Any interrupt or DMA request is asserted.
- There is no card interrupt on the SD_dat1 signal.

As long as the MMC/SD/SDIO controller does not acknowledge the idle request, if an event occurs, the MMC/SD/SDIO host controller can still generate an interrupt or a DMA request. In this case, the module ignores the idle request from the PRCM.

As soon as the MMC/SD/SDIO controller acknowledges the idle request from the PRCM:

- If Smart-Idle modethe module does not assert any new interrupt or DMA request
- If Smart-Idle wake-up-capable modethe module may generate wake-up events related to interrupt or DMA request.

17.3.3.4 Transition from Smart-Idle Mode to Normal Mode

The MMC/SD/SDIO host controller detects the end of the idle period when the PRCM deasserts the idle request. For the wake-up event, there is a corresponding interrupt status in the SD_STAT register. The MMC/SD/SDIO host controller operates the conversion between wake-up and interrupt (or DMA request) upon exit from smart-idle mode if the associated enable bit is set in the SD_ISE register.

Interrupts and wake-up events have independent enable/disable controls, accessible through the SD_HCTL and SD_ISE registers. The overall consistency must be ensured by software.

The interrupt status register SD_STAT is updated with the event that caused the wake-up in the CIRQ bit when the SD_IE[8] CIRQ_ENABLE associated bit is enabled. Then, the wake-up event at the origin of the transition from smart-idle mode to normal mode is converted into its corresponding interrupt or DMA request. (The SD_STAT register is updated and the status of the interrupt signal changes.)

When the idle request from the PRCM is deasserted, the module switches back to normal mode. The module is fully operational.

17.3.3.5 Force-Idle Mode

Force-idle mode is enabled when the SD_SYSCONFIG[4:3] SIDLEMODE bit field is cleared to 0. Force-idle mode is an idle mode where the MMC/SD/SDIO host controller responds unconditionally to the idle request from the PRCM. Moreover, in this mode, the MMC/SD/SDIO host controller unconditionally deasserts interrupts and DMA request lines are asserted.

The transition from normal mode to force-idle mode does not affect the bits of the SD_STAT register. In force-idle mode, the interrupt and DMA request lines are deasserted. Interface Clock (OCP) and functional clock (CLKADPI) can be switched off.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

CAUTION

In Force-ilde mode, an idle request from the PRCM during a command or a data transfer can lead to an unexpected and unpredictable result. When the module is idle, any access to the module generates an error as long as the OCP clock is alive.

The module exits the force-idle mode when the PRCM deassertes the idle request. Then the module switches back to normal mode. The module is fully operational. Interrupt and DMA request lines are optionally asserted one clock cycle later.

17.3.3.6 Local Power Management

Table 17-9 describes power-management features available for the MMC/SD/SDIO modules.

Table 17-9. Local Power Management Features

Feature	Registers	Description
Clock Auto Gating	SD_SYSCONFIG AUTOIDLE bit	This bit allows a local power optimization inside module, by gating the OCP clock upon the interface activity or gating the CLKADPI clock upon the internal activity.
Slave Idle Modes	SD_SYSCONFIG SIDLEMODE bit	Force-idle, No-idle, and Smart-idle modes
Clock Activity	SD_SYSCONFIG CLOCKACTIVITY bit	Please see Table 17-10 for configuration details.
Master Standby Modes	SD_SYSCONFIG STANDYBYMODE bit	Force-idle, No-idle, and Smart-idle modes
Global Wake-Up Enable	SD_SYSCONFIG ENAWAKEUP bit	This bit enables the wake-up feature at module level.
Wake-Up Sources Enable	SD_HCTL register	This register holds one active high enable bit per event source able to generate wake-up signal.

Table 17-10. Clock Activity Settings

CLOCKACTIVITY Values	Clock State When Module is in IDLE State		Features Available when Module is in IDLE State	Wake-Up Events
	OCP Clock	CLKADPI		
00	OFF	OFF	None	Card Interrupt
10	OFF	ON	None	
01	ON	OFF	None	
11	ON	ON	All	

CAUTION

The PRCM module has no hardware means of reading CLOCKACTIVITY settings. Thus, software must ensure consistent programming between the CLOCKACTIVITY and MMC clock PRCM control bits.

17.3.4 Interrupt Requests

Several internal module events can generate an interrupt. Each interrupt has a status bit, an interrupt enable bit, and a signal status enable:

- The status of each type of interrupt is automatically updated in the SD_STAT register; it indicates which service is required.
- The interrupt status enable bits of the SD_IE register enable/disable the automatic update of the SD_STAT register on an event-by-event basis.
- The interrupt signal enable bits of the SD_ISE register enable/disable the transmission of an interrupt request on the interrupt line MMC_IRQ (from the MMC/SD/SDIOi host controller to the MPU subsystem interrupt controller) on an event-by-event basis.

If an interrupt status is disabled in the SD_IE register, then the corresponding interrupt request is not transmitted, and the value of the corresponding interrupt signal enable in the SD_ISE register is ignored.

When an interrupt event occurs, the corresponding status bit is automatically set to 1 (the MMC/SD/SDIO host controller updates the status bit) in the SD_STAT register. If later a mask is applied on the interrupt in the SD_ISE register, the interrupt request is deactivated.

When the interrupt source has not been serviced, if the interrupt status is cleared in the SD_STAT register and the corresponding mask is removed from the SD_ISE register, the interrupt status is not asserted again in the SD_STAT register and the MMC/SD/SDIOi host controller does not transmit an interrupt request.

CAUTION

If the buffer write ready interrupt (BWR) or the buffer read ready only interrupt (BRR) are not serviced and are cleared in the SD_STAT register, and the corresponding mask is removed, then the MMC/SD/SDIOi host controller will wait for the service of the interrupt without updating the status SD_STAT or transmitting an interrupt request.

Table 17-11 lists the event flags, and their mask, that can cause module interrupts.

Table 17-11. Events

Event Flag	Event Mask	Map To	Description
SD_STAT[29] BADA	SD_IE[29] BADA_ENABLE	MMC_IRQ	Bad Access to Data space. This bit is set automatically to indicate a bad access to buffer when not allowed. This bit is set during a read access to the data register (SD_DATA) while buffer reads are not allowed (SD_PSTATE[11] BRE=0). This bit is set during a write access to the data register (SD_DATA) while buffer writes are not allowed (SD_STATE[10] BWE=0)
SD_STAT[28] CERR	SD_IE[28] CERR_ENABLE	MMC_IRQ	Card Error. This bit is set automatically when there is at least one error in a response of type R1, R1b, R6, R5 or R5b. Only bits referenced as type E(error) in status field in the response can set a card status error. An error bit in the response is flagged only if corresponding bit in card status response errros SD_CSRE is set. There is not card detection for auto CMD12 command.
SD_STAT[25] ADMAE	SD_IE[25] ADMAE_ENABLE	MMC_IRQ	AMDA error. This bit is set when the host controller detects errors during ADMA based data transfer. The stat of the ADMA at an error occurrence is saved in the ADMA Error Status Register. In addition, the host controller generates this interrupt when it detects invalid descriptor data (Valid=0) at teh ST_FDS state.
SD_STAT[24] ACE	SD_IE[24] ACE_ENABLE	MMC_IRQ	Auto CMD12 error. This bit is set automatically when one of the bits in Auto CMD12 Error status register has changed from 0 to 1
SD_STAT[22] DEB	SD_IE[22] DEB_ENABLE	MMC_IRQ	Data End Bit error. This bit is set automatically when detecting a 0 at the end bit position of read data on DAT line or at the end position of the CRC status in write mode.

DRAFT ONLY

Table 17-11. Events (continued)

Event Flag	Event Mask	Map To	Description
SD_STAT[21] DCRC	SD_IE[21] DCRC_ENABLE	MMC_IRQ	Data CRC error. This bit is set automatically when there is a CRC16 error in the data phase response following a block read command or if there is a 3-bit CRC status different of a position "010" token during a block write command.
SD_STAT[20] DTO	SD_IE[20] DTO_ENABLE	MMC_IRQ	Data Timeout error. This bit is set automatically according to the following conidtions: A) busy timeout for R1b, R5b response. B) busty timeout after write CRC status. C) write CRC status timeout, or D) read data timeout.
SD_STAT[19] CIE	SD_IE[19] CIE_ENABLE	MMC_IRQ	Command Index Error. This bit is set automatically when response index differs from corresponding command index previously emitted. The check is enabled through SD_CMD[20] CICE bit.
SD_STAT[18] CEB	SD_IE[18] CEB_ENABLE	MMC_IRQ	Command End Bit error. This bit is set automatically when detecting a 0 at the end bit position of a command response.
SD_STAT[17] CCRC	SD_IE[17] CCRC_ENABLE	MMC_IRQ	Command CRC error. This bit is set automatically when there is a CRC7 error in the command response. CRC check is enabled through the SD_CMD[19] CCCE bit.
SD_STAT[16] CTO	SD_IE[16] CTO_ENABLE	MMC_IRQ	Command Timeout error. This bit is set automatically when no response is received within 64 clock cycles from the end bit of the command. For commands the reply within 5 clock cycles, the timeout is still detected at 64 clock cycles.
SD_STAT[15] ERRI	SD_IE[15] ERRI_ENABLE	MMC_IRQ	Error Interrupt. If any of the bits in the Error Interrupt Status register (SD_STAT[24:15]) are set, the this bit is set to 1.
SD_STAT[10] BSR	SD_IE[10] BSR_ENABLE	MMC_IRQ	Boot Status Receieved interrupt. This bit is set automatically when SD_CON[18] BOOT_CF0 is set to 1 or 2h and boot status is received on the dat0 line. This interrupt is only used for MMC cards.
SD_STAT[8] CIRQ	SD_IE[8] CIRQ_ENABLE	MMC_IRQ	Card Interrupt. This bit is only used for SD, SDIO, and CE-ATA cards. In 1-bit mode, interrupt source is asynchronous (can be a source of asynchronous wake-up). In 4-bit mode, interrupt source is sampled during the interrupt cycle. In CE-ATA mode, interrupt source is detected when the card drive CMD line to zero during one cycle after data transmission end.
SD_STAT[5] BRR	SD_IE[5] BRR_ENABLE	MMC_IRQ	Buffer Read ready. This bit is set automatically during a read operation to the card when one block specified by SD_BLK[10:0] BLEN is completely written in the buffer. It indicates that the memory card has filled out the buffger and the local host needs to empty the buffer by reading it.
SD_STAT[4] BWR	SD_IE[4] BWR_ENABLE	MMC_IRQ	Buffer Write ready. This bit is automatically set during a write operation to the card when the host can write a complete block as specified by SD_BLK[10:0] BLEN. It indicates that the memory card has emptied one block from the bugger and the local host is able to write one block of data into the buffer.
SD_STAT[3] DMA	SD_IE[3] DMA_ENABLE	MMC_IRQ	DMA interrupt. This status is set when an interrupt is required in the AMDA instruction and after the data transfer is complete.
SD_STAT[2] BGE	SD_IE[2] BGE_ENABLE	MMC_IRQ	Block Gap event. When a stop at block gap is requested (SD_HCTL[16] SBGR), this bit is automatically set when transaction is stopped at the block gap during a read or write operation.
SD_STAT[1] TC	SD_IE[1] TC_ENABLE	MMC_IRQ	Transfer completed. This bit is always set when a read/write transfer is completed or between two blocks when the transfer is stopped due to a stop at block gap requesd (SD_HCTL[16 SBGR). In read mode this bit is automatically set on completion of a read transfer (SD_PSTATE[9] RTA). In write mode, this bit is automatically set on completion of the DAT line use (SD_PSTATE[2] DLA).
SD_STAT[0] CC	SD_IE[0] CC_ENABLE	MMC_IRQ	Command complete. This bit is set when a 1-to-0 transition occurs in the register command inhibit (SD_PSTATE[0] CMDI). If the command is a type for which no response is expected, then the command complete interrupt is generated at the end of the command. A command timeout error (SD_STAT[16] CTO) has higher priority than command complete (SD_STAT[0] CC). If a response is expected but none is received, the a Command Timeout error is detected and signaled instead of the Command Complete interrupt.

17.3.4.1 Interrupt-Driven Operation

An interrupt enable bit must be set in the SD_IE register to enable the module internal source of interrupt.

When an interrupt event occurs, the single interrupt line is asserted and the LH must:

- Read the SD_STAT register to identify which event occurred.
- Write 1 into the corresponding bit of the SD_STAT register to clear the interrupt status and release the interrupt line (if a read is done after this write, this would return 0).

NOTE: In the SD_STAT register, Card Interrupt (CIRQ) and Error Interrupt (ERRI) bits cannot be cleared.

The SD_STAT[8] CIRQ status bit must be masked by disabling the SD_IE[8] CIRQ_ENABLE bit (cleared to 0), then the interrupt routine must clear SDIO interrupt source in SDIO card common control register (CCCR).

The SD_STAT[15] ERRI bit is automatically cleared when all status bits in SD_STAT[31:16] are cleared.

17.3.4.2 Polling

When the interrupt capability of an event is disabled in the SD_ISE register, the interrupt line is not asserted:

- Software can poll the status bit in the SD_STAT register to detect when the corresponding event occurs.
- Writing 1 into the corresponding bit of the SD_STAT register clears the interrupt status and does not affect the interrupt line state.

NOTE: Please see the note in Section 17.3.4.1 concerning CIRQ and ERRI bits clearing.

17.3.5 DMA Modes

The device supports DMA slave mode only. In this case, the controller is slave on DMA transaction managed by two separated requests (SDMAWREQN and SDMARREQN)

17.3.5.1 DMA Slave Mode Operations

The MMC/SD/SDIO controller can be interfaced with a DMA controller. At system level, the advantage is to discharge the local host (LH) of the data transfers. The module does not support wide DMA access (above 1024 bytes) for SD cards as specified in the *SD Card Specification*and *SD Host Controller Standard Specification*.

The DMA request is issued if the following conditions are met:

- The SD_CMD[0] DE bit is set to 1 to trigger the initial DMA request (the write must be done when running the data transfer command).
- A command was emitted on the SD_cmd line.
- There is enough space in the buffer of the MMC/SD/SDIO controller to write an entire block (BLEN writes).

DRAFT ONLY

17.3.5.1.1 DMA Receive Mode

In a DMA block read operation (single or multiple), the request signal SDMARREQN is asserted to its active level when a complete block is written in the buffer. The block size transfer is specified in the SD_BLK[10:0] BLEN field.

The SDMARREQN signal is deasserted to its inactive level when the sDMA has read one single word from the buffer. Only one request is sent per block; the DMA controller can make a 1-shot read access or several DMA bursts, in which case the DMA controller must manage the number of burst accesses, according to block size BLEN field.

New DMA requests are internally masked if the sDMA has not read exactly BLEN bytes and a new complete block is not ready. As DMA accesses are in 32-bit, then the number of sDMA read is Integer(BLEN/4)+1.

The receive buffer never overflows. In multiple block transfers for block size above 512 bytes, when the buffer gets full, the MMC_CLK clock signal (provided to the card) is momentarily stopped until the sDMA or the MPU performs a read access, which reads a complete block in the buffer.

Figure 17-17 provides a summary:

- DMA transfer size = BLEN buffer size in one shot or by burst
- One DMA request per block

Figure 17-17. DMA Receive Mode

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

17.3.5.1.2 DMA Transmit Mode

In a DMA block write operation (single or multiple), the request signal SDMAWREQN is asserted to its active level when a complete block is to be written to the buffer. The block size transfer is specified in the SD_BLK[10:0] BLEN field.

The SDMAWREQN signal is deasserted to its inactive level when the sDMA has written one single word to the buffer.

Only one request is sent per block; the DMA controller can make a 1-shot write access or multiple write DMA bursts, in which case the DMA controller must manage the number of burst accesses, according to block size BLEN field.

New DMA requests are internally masked if the sDMA has not written exactly BLEN bytes (as DMA accesses are in 32-bit, then the number of sDMA read is Integer(BLEN/4)+1) and if there is not enough memory space to write a complete block in the buffer.

Figure 17-18 provides a summary:

- DMA transfer size = BLEN buffer size in one shot or by burst
- One DMA request per block

Figure 17-18. DMA Transmit Mode

17.3.6 Mode Selection

The MMC/SD/SDIO host controller can be use in two modes, MMC and SD/SDIO modes. It has been designed to be the most transparent with the type of card. The type of the card connected is differentiated by the software initialization procedure.

Software identifies the type of card connected during software initialization. For each given card type, there are corresponding commands. Some commands are not supported by all cards. See the *Multimedia Card System Specification*, the *SD Memory Card Specifications*, and the *SDIO Card Specification, Part E1* for more details.

The purpose of the module is to transfer commands and data, to whatever card is connected, respecting the protocol of the connected card. Writes and reads to the card must respect the appropriate protocol of that card.

17.3.7 Buffer Management

17.3.7.1 Data Buffer

The MMC/SD/SDIO host controller uses a data buffer. This buffer transfers data from one data bus (Interconnect) to another data bus (SD, SDIO, or MMC card bus) and vice versa.

The buffer is the heart of the interface and ensures the transfer between the two interfaces (L4 and the card). To enhance performance, the data buffer is completed by a prefetch register and a post-write buffer that are not accessible by the host controller.

The read access time of the prefetch register is faster than the one of the data buffer. The prefetch register allows data to be read from the data buffer at an increased speed by preloading data into the prefetch register.

The entry point of the data buffer, the prefetch buffer, and the post-write buffer is the 32-bit register SD_DATA. A write access to the SD_DATA register followed by a read access from the SD_DATA register corresponds to a write access to the post-write buffer followed by a read access to the prefetch buffer. As a consequence, it is normal that the data of the write access to the SD_DATA register and the data of the read access to the SD_DATA register are different.

The number of 32-bit accesses to the SD_DATA register that are needed to read (or write) a data block with a size of SD_BLK[10:0] BLEN, and equals the rounded up result of BLEN divided by 4. The maximum block size supported by the host controller is hard-coded in the register SD_CAPA[17:16] MBL field and cannot be changed.

A read access to the SD_DATA register is allowed only when the buffer read enable status is set to 1 (SD_PSTATE[11] BRE); otherwise, a bad access (SD_STAT[29] BADA) is signaled.

A write access to the SD_DATA register is allowed only when the buffer write enable status is set to 1 (SD_PSTATE[10] BWE); otherwise, a bad access (SD_STAT[29] BADA) is signaled and the data is not written.

The data buffer has two modes of operation to store and read of the first and second portions of the data buffer:

- When the size of the data block to transfer is less than or equal to MEM_SIZE/2 (in double buffering), two data transfers can occur from one data bus to the other data bus and vice versa at the same time. The MMC/SD/SDIO controller uses the two portions of the data buffer in a ping-pong manner so that storing and reading of the first and second portions of the data buffer are automatically interchanged from time to time so that data may be read from one portion (for instance, through a DMA read access on the interconnect bus) while data (for instance, from the card) is being stored into the other portion and vice versa. When BLEN is less than or equal to 200h (that is, less or equal to 512Bytes), each of the two portions of the buffer that can be used have a size of BLEN (that is, 32-bits x BLEN div by 4). Not more than this total size of 2 times 32-bits × BLEN div by 4 can be used.
- When the size of the data block to transfer is larger than MEM_SIZE/2, only one data transfer can occur from one data bus to the other data bus at a time. The MMC/SD/SDIO host controller uses the entire data buffer as a single portion. In this mode, a bad access (SD_STAT[29] BADA) is signaled when two data transfers occur from one data bus to the other data bus and vice versa at the same time.

Copyright © 2011, Texas Instruments Incorporated

CAUTION

The SD_CMD[4] DDIR bit must be configured before a transfer to indicate the direction of the transfer.

Figure 17-19 shows the buffer management for writing and Figure 17-20 shows the buffer management for reading.

17.3.7.1.2 Data Buffer Status

The data buffer status is defined in the following interrupt status register and status register:

- Interrupt status registers (see Figure 17-58):
  - SD_STAT[29] BADABad access to data space
  - SD_STAT[5] BRRBuffer read ready
  - SD_STAT[4] BWRBuffer write ready
- Status registers (see Figure 17-55):
  - SD_PSTATE[11] BREBuffer read enable
  - SD_PSTATE[10] BWEBuffer write enable

17.3.8 Transfer Process

The process of a transfer is dependent on the type of command. It can be with or without a response, with or without data.

17.3.8.1 Different Types of Commands

Different types of commands are specific to MMC, SD, or SDIO cards. See the *Multimedia Card System Specification*, the *SD Memory Card Specifications*, the *SDIO Card Specification, Part E1*, or the *SD Card Specification, Part A2, SD Host Controller Standard Specification* for more details.

17.3.8.2 Different Types of Responses

Different types of responses are specific to MMC, SD, or SDIO cards. See the *Multimedia Card System Specification*, the *SD Memory Card Specifications*, the *SDIO Card Specification, Part E1*, or the *SD Card Specification, Part A2, SD Host Controller Standard Specification* for more details.

Table 17-13 shows how the MMC, SD, and SDIO responses are stored in the SD_RSPxx registers.

Table 17-13. MMC, SD, SDIO Responses in the SD_RSPxx Registers

Kind of Response	Response Field	Response Register
R1, R1b (normal response), R3, R4, R5, R5b, R6, R7	RESP[39:8][(1)]	SD_RSP10[31:0]
R1b (Auto CMD12 response)	RESP[39:8][(1)]	SD_RSP76[31:0]
R2	RESP[127:0][(1)]	SD_RSP76[31:0] SD_RSP54[31:0] SD_RSP32[31:0] SD_RSP10[31:0]

(1) RESP refers to the command response format described in the specifications mentioned above.

When the host controller modifies part of the SD_RSPxx registers, it preserves the unmodified bits.

The host controller stores the Auto CMD12 response in the SD_RSP76[31:0] register because the Host Controller may have a multiple block data DAT line transfer executing concurrently with a command. This allows the host controller to avoid overwriting the Auto CMD12 response with the command response stored in SD_RSP10 register and vice versa.

17.3.9 Transfer or Command Status and Error Reporting

Flags in the MMC/SD/SDIO host controller show status of communication with the card:

- A timeout (of a command, a data, or a response)
- A CRC

Error conditions generate interrupts. See Table 17-14 and register description for more details.

Table 17-14. CC and TC Values Upon Error Detected

Error hold in the SD_STAT Register		CC	TC	Comments
29	BADA			No dependency with CC or TC. BADA is related to the register accesses. Its assertion is not dependent of the ongoing transfer.
28	CERR	1		CC is set upon CERR.
22	DEB		1	TC is set upon DEB.
21	DCRC		1	TC is set upon DCRC.
20	DTO			DTO and TC are mutually exclusive. DCRC and DEB cannot occur with DTO.
19	CIE	1		CC is set upon CIE.
18	CEB	1		CC is set upon CEB.
17	CCRC	1		CC can be set upon CCRC - See CTO comment
16	CTO			CTO and CC are mutually exclusive. CIE, CEB and CERR cannot occur with CTO. CTO can occur at the same time as CCRCit indicates a command abort due to a contention on CMD line. In this case no CC appears.

SD_STAT[21] DCRC event can be asserted in the following conditions:

- Busy timeout for R1b, R5b response type
- Busy timeout after write CRC status
- Write CRC status timeout
- Read data timeout
- Boot acknowledge timeout

17.3.10 Auto Command 12 Timings

With the UHS definition of SD cards with higher frequency for MMC clocks up to 208, SD standard imposes a specific timing for Auto CMD12 "end bit" arrival.

17.3.10.1 Auto Command 12 Timings During Write Transfer

A margin named Ncrc in range of 2 to 8 cycles has been defined for SDR50 and SDR104 card components for write data transfers, as auto command 12 'end bit' shall arrive after the CRC status "end bit".

Figure 17-27 shows auto CMD12 timings during write transfer.

Figure 17-27. Auto CMD12 Timing During Write Transfer

The Host controller has a margin of 18 clock cycles to make sure that auto CMD12 'end bit' arrives after the CRC status. This margin does not depend on MMC bus configuration, DDR or standard transfer, 1,4 or 8 bus width.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

17.3.10.2 Auto Command 12 Timings During Read Transfer

With UHS very high speed cards gap timing between 2 successive cards has been extended to 4 cycles instead of 2. By the way it gives more flexibility for Host Auto CMD12 arrival in order to receive the last complete and reliable block. SD controller only follows the 'Left Border Case' defined by SD UHS specification.

Figure 17-28 shows ACMD12 timings during read transfer.

Figure 17-28. Auto Command 12 Timings During Read Transfer

The Auto CMD12 arrival sent by the Host controller is not sensitive to the MMC bus configuration whether it is DDR or standard transfer and whether it is a 1,4 or 8 bit bus width transfer.

DRAFT ONLY

17.3.11 Transfer Stop

Whenever a transfer is initiated, the transmission may be willed to stop whereas it is still not finished. Several cases can be faced depending on the transfer type:

- Multiple blocks oriented transfers (for which transfer length is known)
- Continuous stream transfers (which have an infinite length)

NOTE: Since the MMC/SD/SDIO controller manages transfers based on a block granularity, the buffer will accept a block only if there is enough space to completely store it. Consequently, if a block is pending in the buffer, no command will be sent to the card because the card clock will be shut off by the controller.

The MMC/SD/SDIO controller includes two features which make a transfer stop more convenient and easier to manage:

- Auto CMD12 (for MMC and SD only).

  This feature is enabled by setting the SD_CMD[2] ACEN bit to 1 (this setting is relevant for a MMC/SD transfer with a known number of blocks to transfer). When the Auto CMD12 feature is enabled, the MMC/SD/SDIO controller will automatically issue a CMD12 command when the expected number of blocks has been exchanged.
- Stop at block gap

  This feature is enabled by setting the SD_HCTL[16] SBGR bit to 1. When enabled, this capability holds the transfer on until the end of a block boundary. If a stop transmission is needed, software can use this pause to send a CMD12 to the card.

Table 17-15 shows the common ways to stop a transfer, indicating command to send and features to enable.

Table 17-15. MMC/SD/SDIO Controller Transfer Stop Command Summary

		WRITE Transfer		READ Transfer	
		MMC/SD	SDIO	MMC/SD	SDIO
Single block		Transfer ends automatically Wait TC	Transfer ends automatically Wait TC	Transfer ends automatically Wait TC	Transfer ends automatically Wait TC
Multi blocks (finite or infinite)	Before the programmed block boundary	Send CMD12 Wait TC	Send CMD52 Wait TC	Send CMD12 Wait TC	Send CMD52 Wait TC
	Stop at the end of the transfer (finite transfer only)	Auto CMD12 active Transfer ends automatically Wait TC	Set SD_HCTL[16] SBGR bit to 1. Send CMD52 Wait TC	Auto CMD12 active Transfer ends automatically Wait TC	**If READ_WAIT supported** Stop at block gap Wait TC
					If READ_WAIT not supported Send CMD52 Wait TC

NOTE: The MMC/SD/SDIO controller will send the stop command to the card on a block boundary, regardless the moment the command was written to the controller registers.

17.3.12 Output Signals Generation

The MMC/SD/SDIO output signals can be driven on either falling edge or rising edge depending on the SD_HCTL[2] HSPE bit. This feature allows to reach better timing performance, and thus to increase data transfer frequency.

17.3.12.1 Generation on Falling Edge of MMC Clock

The controller is by default in this mode to maximize hold timings. In this case, SD_HCTL[2] HSPE bit is cleared to 0.

Figure 17-29 shows the output signals of the module when generating from the falling edge of the MMC clock.

Figure 17-29. Output Driven on Falling Edge

17.3.12.2 Generation on Rising Edge of MMC Clock

This mode increases setup timings and allows reaching higher bus frequency. This feature is activated by setting SD_HCTL[2] HSPE bit to 1. The controller shall be set in this mode to support SDR transfers.

NOTE: Do not use this feature in Dual Data Rate mode (when SD_CON[19] DDR is set to 1).

Figure 17-30 shows the output signals of the module when generating from the rising edge of the MMC clock.

17.3.13 Card Boot Mode Management

Boot Operation Mode allows the MMC/SD/SDIO host controller to read boot data from the connected slave (MMC device) by keeping CMD line low after power-on (or sending CMD0 with specific argument) before issuing CMD1. The data can be read from either boot area or user area, depending on register setting. Power-on boot defines a way for the boot-code to be accessed by the MMC/SD/SDIO host controller without an upper-level software driver, speeding the time it takes for a controller to access the boot code.

The two possible ways to issue a boot command (either issuing a CMD0 or driving the CMD line to 0 during the whole boot phase) are described in the following sections.

17.3.13.1 Boot Mode Using CMD0

Figure 17-31 shows the timing diagram of a boot sequence using CMD0.

Figure 17-31. Boot Mode With CMD0

* Refer to MMC Specification for correct argument.

17.3.13.2 Boot Mode With CMD Held Low

Figure 17-32 shows the timing diagram of a boot sequence with CMD line tied to 0.

Figure 17-32. Boot Mode With CMD Line Tied to 0

For more information on how to configure the MMC/SD/SDIO host controller, see the section titled Boot with CMD line tied to 0.

17.3.14 CE-ATA Command Completion Disable Management

The MMC/SD/SDIO controller supports CE-ATA features, in particular the detection of command completion token. When a command that requires a command completion signal (SD_CON[12] CEATA and SD_CMD[2] ACEN set to 1) is launched, the host system is no longer allowed to emit a new command in parallel of data transfer unless it is a command completion disable token.

The settings to emit a command completion disable token follow:

- SD_CON[12] CEATA is set to 1.
- SD_CON[2] HR set to 1.
- Clear the SD_ARG register.
- Write into SD_CMD register with value 0000 0000h.

When a command completion disable token was emitted (that is, SD_STAT[0] CC received), the host system is again allowed to emit another type of command (for example a transfer abort command CMD12 to abort transfer).

A critical case can be met when command completion signal disable (CCSD) is emitted during the last data block transfer, the sequence on command line could be sent very close to command completion signal (CCS) token sent by the card.

Three cases can be met:

- CCS is receive just before CCSD is emitted:

  An interrupt CIRQ is generated with CCS detection, CCSD is transmitted to card then an interrupt CC is generated when CCSD ends. In this case, card consider the CCSD sequence.
- CCS is not generated or generated during the CCSD transfer:

  The CCS bit cannot be detected (conflict is not possible as they drive the same level on command line, then no CIRQ interrupt is generated; besides CC interrupt is generated when CCSD ends).
- CCS is generated without CCSD token required:

  Only the interrupt CIRQ is generated when CCS is detected.

17.3.15 Test Registers

Test registers are available to be compliant with SD Host controller specification. This feature is useful to generate interrupts manually for driver debugging. The Force Event register (SD_FE) is used to control the Error Interrupt Status and Auto CMD12 Error Status. The System Test register (SD_SYSTEST) is used to control the signals that connect to I/O pins when the module is configured in system test (SD_CON[4] MODE = 1) mode for boundary connectivity verification.

17.3.16 MMC/SD/SDIO Hardware Status Features

Table 17-16 summarizes the MMC/SD/SDIO hardware status features.

Table 17-16. MMC/SD/SDIO Hardware Status Features

Feature	Type	Register/Bit Field/Observability Control	Description
Interrupt flags		See Section 17.3.4.	
CMD line signal level	Status	[24] CLEV	Indicates the level of the cmd line
DAT lines signal level	Status	[23:20] DLEV	Indicates the level of the data lines
Buffer read enable	Status	[11] BRE	Readable data exists in the buffer.
Buffer write enable	Status	[10] BWE	Indicates whether there is enough space in the buffer to write BLEN bytes of data
Read transfer active	Status	[9] RTA	This status is used for detecting completion of a read transfer.
Write transfer active	Status	[8] WTA	This status indicates a write transfer active.
Data line active	Status	[2] DLA	Indicates whether the data lines are active
Command Inhibit (data lines)	Status	[1] DATI	Indicates whether issuing of command using data lines is allowed
Command inhibit (CMD line)	Status	[0] CMDI	Indicates whether issuing of command using CMD line is allowed

17.3.17 Low-Level Programming Models

17.3.17.1 Surrounding Modules Global Initialization

This section identifies the requirements of initializing the surrounding modules when the module has to be used for the first time after a device reset. This initialization of surrounding modules is based on the integration and environment of the MMC/SD/SDIO modules.

Table 17-17. Global Init for Surrounding Modules

Surrounding Modules	Comments
PRCM	Module interface and functional clocks must be enabled. For more information, see Power, Reset, and Clock Management (PRCM) chapter
Control module	Module-specific pad muxing and configuration must be set in the control module. See Control Module chapter.
(optional) MPU INTC	MPU INTC configuration must be done to enable the interrupts from the SD module. See Interrupt Controller chapter
(optional) sDMA (or dDMA)	DMA configuration must be done to enable the module DMA channel requests. See SDMA chapter
(optional) Interconnect	For more information about the interconnect configuration, see Interconnect chapter

NOTE: The MPU interrupt controller and the sDMA/dDMA configurations are necessary, if the interrupt and DMA based communication modes are used.

17.3.17.2 MMC/SD/SDIO Controller Initialization Flow

The next sections outline the four steps to initialize the MMC/SD/SDIO controller:

- Initialize Clocks
- Software reset of the controller
- Set module's hardware capabilities
- Set module's Idle and Wake-Up modes

17.3.17.2.1 Enable OCP and CLKADPI Clocks

Prior to any SD register access one must enable the SD OCP clock and CLKADPI clock in PRCM module registers. Refer to the *Power, Reset, and Clock Management* chapter.

17.3.17.3 Operational Modes Configuration

17.3.17.3.1 Basic Operations for MMC/SD/SDIO Host Controller

The MMC/SD/SDIO controller performs data transfers: data to card (referred to as write transfers) and data from card (referred to as read transfers).

The host controller requires transfers to run on a block-by-block basis, rather than on a DMA burst size basis. A single DMA request (or block request interrupt) is signaled for each block. Pipelining is supported as long as the block size is less than one half of the memory buffer size.

17.3.17.3.2 Card Detection, Identification, and Selection

Figure 17-35 and Figure 17-36 show the card identification and selection process.

LEGENDR/W = Read/Write; R = Read only; -*n* = value after reset

Table 17-20. System Configuration Register (SD_SYSCONFIG) Field Descriptions

Bit	Field	Value	Description
31-14	Reserved	0	These bits are initialized to zero, and writes to them are ignored. Reads return 0.
13-12	STANDBYMODE		Master interface power Management, standby/wait control. The bit field is only useful when generic parameter MADMA_EN (Master ADMA enable) is set as active, otherwise it is a read only register read a 0.
		0	Force-standby. Mstandby is forced unconditionally.
		1h	No-standby. Mstandby is never asserted.
		2h	Smart-standby modelocal initiator standby status depends on local conditions, i.e. the module's functional requirement from the initiator. IP module shall not generate (initiator-related) wake-up events.
		3h	Smart-Standby wake-up-capable modelocal initiator standby status depends on local conditions, i.e. the module's functional requirement from the initiator. IP module can generate (master-related) wake-up events when in standby state. Mode is only relevant if the appropriate IP module "mwake-up" output is implemented. Functional clock is maintained. Interface clock may be switched off.
11-10	Reserved	0	These bits are initialized to zero, and writes to them are ignored. Reads return 0.
9-8	CLOCKACTIVITY		Clocks activity during wake up mode period.
		Bit 8	Interface clock
		Bit 9	Functional clock
		0	Interface and Functional clock may be switched off.
		1h	Interface clock is maintained. Functional clock may be switched-off.
		2h	Functional clock is maintained. Interface clock may be switched-off.
		3h	Interface and Functional clocks are maintained.
7-5	Reserved	0	These bits are initialized to zero, and writes to them are ignored. Reads return 0.
4-3	SIDLEMODE		Power management
		0	If an idle request is detected, the MMC/SD/SDIO host controller acknowledges it unconditionally and goes in Inactive mode. Interrupt and DMA requests are unconditionally deasserted.
		1h	If an idle request is detected, the request is ignored and the module keeps on behaving normally.
		2h	If an idle request is detected, the module will switch to wake up mode based on its internal activity, and the wake up capability can be used if the wake up capability is enabled (bit SD_SYSCONFIG[2] ENAWAKEUP bit is set to 1).
		3h	Smart-idle Wake-up capable modelocal target's idle state eventually acknowledges the system's idle requests, depending on the IP modules internal requirements. IP module may generate (IRQ- or DMA-request-related) wake-up events when in idle state. Mode is only relevant if the appropriate IP module "swake-up" output(s) is (are) implemented.

17.5.5 System Status Register (SD_SYSSTATUS)

This register provides status information about the module excluding the interrupt status information. The system status register (SD_SYSSTATUS) is shown in Figure 17-41 and described in Table 17-21.

Figure 17-41. System Status Register (SD_SYSSTATUS)

31	1	0
Reserved		RESETDONE
R-0		R-0

LEGENDR/W = Read/Write; R = Read only; -*n* = value after reset

Bit	Field	Value	Description
31-1	Reserved	0	Reserved bit field. Do not write any value.
0	RESETDONE		Internal Reset Monitoring. Notethe debounce clock , the interface clock and the functional clock shall be provided to the MMC/SD/SDIO host controller to allow the internal reset monitoring.
		Read 0	Internal module reset is on-going
		Read 1	Reset completed

17.5.6 Card Status Response Error (SD_CSRE)

This register enables the host controller to detect card status errors of response type R1, R1b for all cards and of R5, R5b and R6 response for cards types SD or SDIO. When a bit SD_CSRE[i] is set to 1, if the corresponding bit at the same position in the response SD_RSP10[I] is set to 1, the host controller indicates a card error (SD_STAT[28] CERR bit) interrupt status to avoid the host driver reading the response register (SD_RSP10).

NOTE: No automatic card error detection for autoCMD12 is implemented; the host system has to check autoCMD12 response register (SD_RSP76) for possible card errors.

The card status response error (SD_CSRE) is shown in Figure 17-42 and described in Table 17-22.

Figure 17-42. Card Status Response Error (SD_CSRE)

17.5.7 System Test Register (SD_SYSTEST)

This register is used to control the signals that connect to I/O pins when the module is configured in system test (SYSTEST) mode for boundary connectivity verification.

NOTE: In SYSTEST mode, a write into SD_CMD register will not start a transfer. The buffer behaves as a stack accessible only by the local host (push and pop operations). In this mode, the Transfer Block Size (SD_BLK[10:0] BLEN bits) and the Blocks count for current transfer (SD_BLK[31:16] NBLK bits) are needed to generate a Buffer write ready interrupt (SD_STAT[4] BWR bit) or a Buffer read ready interrupt (SD_STAT[5] BRR bit) and DMA requests if enabled.

The system test register (SD_SYSTEST) is shown in Figure 17-43 and described in Table 17-23.

Figure 17-43. System Test Register (SD_SYSTEST)

Table 17-23. System Test Register (SD_SYSTEST) Field Descriptions (continued)

Bit	Field	Value	Description
11	D7D		DAT7 input/output signal data value
		Read 0	If SD_SYSTEST[3] DDIR bit = 1 (input mode direction), returns the value on the DAT7 line (low). If SD_SYSTEST[3] DDIR bit = 0 (output mode direction), returns 0.
		Write 0	If SD_SYSTEST[3] DDIR bit = 0 (output mode direction), the DAT7 line is driven low. If SD_SYSTEST[3] DDIR bit = 1 (input mode direction), no effect.
		Read 1	If SD_SYSTEST[3] DDIR bit = 1 (input mode direction), returns the value on the DAT7 line (high) If SD_SYSTEST[3] DDIR bit = 0 (output mode direction), returns 1.
		Write 1	If SD_SYSTEST[3] DDIR bit = 0 (output mode direction), the DAT7 line is driven high. If SD_SYSTEST[3] DDIR bit = 1 (input mode direction), no effect.
10	D6D		DAT6 input/output signal data value
		Read 0	If SD_SYSTEST[3] DDIR bit = 1 (input mode direction), returns the value on the DAT6 line (low). If SD_SYSTEST[3] DDIR bit = 0 (output mode direction), returns 0.
		Write 0	If SD_SYSTEST[3] DDIR bit = 0 (output mode direction), the DAT6 line is driven low. If SD_SYSTEST[3] DDIR bit = 1 (input mode direction), no effect.
		Read 1	If SD_SYSTEST[3] DDIR bit = 1 (input mode direction), returns the value on the DAT6 line (high) If SD_SYSTEST[3] DDIR bit = 0 (output mode direction), returns 1.
		Write 1	If SD_SYSTEST[3] DDIR bit = 0 (output mode direction), the DAT6 line is driven high. If SD_SYSTEST[3] DDIR bit = 1 (input mode direction), no effect.
9	D5D		DAT5 input/output signal data value
		Read 0	If SD_SYSTEST[3] DDIR bit = 1 (input mode direction), returns the value on the DAT5 line (low). If SD_SYSTEST[3] DDIR bit = 0 (output mode direction), returns 0.
		Write 0	If SD_SYSTEST[3] DDIR bit = 0 (output mode direction), the DAT5 line is driven low. If SD_SYSTEST[3] DDIR bit = 1 (input mode direction), no effect.
		Read 1	If SD_SYSTEST[3] DDIR bit = 1 (input mode direction), returns the value on the DAT5 line (high) If SD_SYSTEST[3] DDIR bit = 0 (output mode direction), returns 1.
		Write 1	If SD_SYSTEST[3] DDIR bit = 0 (output mode direction), the DAT5 line is driven high. If SD_SYSTEST[3] DDIR bit = 1 (input mode direction), no effect.
8	D4D		DAT4 input/output signal data value
		Read 0	If SD_SYSTEST[3] DDIR bit = 1 (input mode direction), returns the value on the DAT4 line (low). If SD_SYSTEST[3] DDIR bit = 0 (output mode direction), returns 0.
		Write 0	If SD_SYSTEST[3] DDIR bit = 0 (output mode direction), the DAT4 line is driven low. If SD_SYSTEST[3] DDIR bit = 1 (input mode direction), no effect.
		Read 1	If SD_SYSTEST[3] DDIR bit = 1 (input mode direction), returns the value on the DAT4 line (high) If SD_SYSTEST[3] DDIR bit = 0 (output mode direction), returns 1.
		Write 1	If SD_SYSTEST[3] DDIR bit = 0 (output mode direction), the DAT4 line is driven high. If SD_SYSTEST[3] DDIR bit = 1 (input mode direction), no effect.
7	D3D		DAT3 input/output signal data value
		Read 0	If SD_SYSTEST[3] DDIR bit = 1 (input mode direction), returns the value on the DAT3 line (low). If SD_SYSTEST[3] DDIR bit = 0 (output mode direction), returns 0.
		Write 0	If SD_SYSTEST[3] DDIR bit = 0 (output mode direction), the DAT3 line is driven low. If SD_SYSTEST[3] DDIR bit = 1 (input mode direction), no effect.
		Read 1	If SD_SYSTEST[3] DDIR bit = 1 (input mode direction), returns the value on the DAT3 line (high) If SD_SYSTEST[3] DDIR bit = 0 (output mode direction), returns 1.
		Write 1	If SD_SYSTEST[3] DDIR bit = 0 (output mode direction), the DAT3 line is driven high. If SD_SYSTEST[3] DDIR bit = 1 (input mode direction), no effect.
6	D2D		DAT2 input/output signal data value
		Read 0	If SD_SYSTEST[3] DDIR bit = 1 (input mode direction), returns the value on the DAT2 line (low). If SD_SYSTEST[3] DDIR bit = 0 (output mode direction), returns 0.
		Write 0	If SD_SYSTEST[3] DDIR bit = 0 (output mode direction), the DAT2 line is driven low. If SD_SYSTEST[3] DDIR bit = 1 (input mode direction), no effect.
		Read 1	If SD_SYSTEST[3] DDIR bit = 1 (input mode direction), returns the value on the DAT2 line (high) If SD_SYSTEST[3] DDIR bit = 0 (output mode direction), returns 1.
		Write 1	If SD_SYSTEST[3] DDIR bit = 0 (output mode direction), the DAT2 line is driven high. If SD_SYSTEST[3] DDIR bit = 1 (input mode direction), no effect.

Table 17-23. System Test Register (SD_SYSTEST) Field Descriptions (continued)

Bit	Field	Value	Description
5	D1D		DAT1 input/output signal data value
		Read 0	If SD_SYSTEST[3] DDIR bit = 1 (input mode direction), returns the value on the DAT1 line (low). If SD_SYSTEST[3] DDIR bit = 0 (output mode direction), returns 0.
		Write 0	If SD_SYSTEST[3] DDIR bit = 0 (output mode direction), the DAT1 line is driven low. If SD_SYSTEST[3] DDIR bit = 1 (input mode direction), no effect.
		Read 1	If SD_SYSTEST[3] DDIR bit = 1 (input mode direction), returns the value on the DAT1 line (high) If SD_SYSTEST[3] DDIR bit = 0 (output mode direction), returns 1.
		Write 1	If SD_SYSTEST[3] DDIR bit = 0 (output mode direction), the DAT1 line is driven high. If SD_SYSTEST[3] DDIR bit = 1 (input mode direction), no effect.
4	D0D		DAT0 input/output signal data value
		Read 0	If SD_SYSTEST[3] DDIR bit = 1 (input mode direction), returns the value on the DAT0 line (low). If SD_SYSTEST[3] DDIR bit = 0 (output mode direction), returns 0.
		Write 0	If SD_SYSTEST[3] DDIR bit = 0 (output mode direction), the DAT0 line is driven low. If SD_SYSTEST[3] DDIR bit = 1 (input mode direction), no effect.
		Read 1	If SD_SYSTEST[3] DDIR bit = 1 (input mode direction), returns the value on the DAT0 line (high) If SD_SYSTEST[3] DDIR bit = 0 (output mode direction), returns 1.
		Write 1	If SD_SYSTEST[3] DDIR bit = 0 (output mode direction), the DAT0 line is driven high. If SD_SYSTEST[3] DDIR bit = 1 (input mode direction), no effect.
3	DDIR		Control of the DAT[7:0] pins direction
		Read 0	No action. Returns 0.
		Write 0	The DAT lines are outputs (host to card).
		Read 1	No action. Returns 1.
		Write 1	The DAT lines are inputs (card to host).
2	CDAT		CMD input/output signal data value
		Read 0	If SD_SYSTEST[1] CDIR bit = 1 (input mode direction), returns the value on the CMD line (low). If SD_SYSTEST[1] CDIR bit = 0 (output mode direction), returns 0 .
		Write 0	If SD_SYSTEST[1] CDIR bit = 0 (output mode direction), the CMD line is driven low. If SD_SYSTEST[1] CDIR bit = 1 (input mode direction), no effect.
		Read 1	If SD_SYSTEST[1] CDIR bit = 1 (input mode direction), returns the value on the CMD line (high) If SD_SYSTEST[1] CDIR bit = 0 (output mode direction), returns 1 .
		Write 1	If SD_SYSTEST[1] CDIR bit = 0 (output mode direction), the CMD line is driven high. If SD_SYSTEST[1] CDIR bit = 1 (input mode direction), no effect.
1	CDIR		Control of the CMD pin direction
		Read 0	No action. Returns 0.
		Write 0	The CMD line is an output (host to card).
		Read 1	No action. Returns 1.
		Write 1	The CMD line is an input (card to host) .
0	MCKD		MMC clock output signal data value
		Read 0	No action. Returns 0.
		Write 0	The output clock is driven low.
		Read 1	No action. Returns 1.
		Write 1	The output clock is driven high.

17.5.8 Configuration Register (SD_CON)

This register is used:

- To select the functional mode for any card
- To send an initialization sequence to any card
- To send an initialization sequence to any card
- To enable the detection on the mmc_dat[1] signal of a card interrupt for SDIO cards only

It also configures:

- The parameters related to the card detect and write protect input signals

The configuration register (SD_CON) is shown in Figure 17-44 and described in Table 17-24.

Figure 17-44. Configuration Register (SD_CON)

LEGENDR/W = Read/Write; R = Read only; -*n* = value after reset

Table 17-24. Configuration Register (SD_CON) Field Descriptions

Bit	Field	Value	Description
31-22	Reserved	0	Reserved bit field. Do not write any value.
21	SDMA_LnE		Slave DMA Level/Edge Request. The waveform of the DMA request can be configured either edge sensitive with early de-assertion on first access to SD_DATA register or late de-assertion, request remains active until last allowed data written into SD_DATA.
		0	Slave DMA edge sensitive.
		1	Slave DMA level sensitive.
20	DMA_MnS		DMA Master or Slave selection. When this bit is set and the controller is configured to use the DMA, Ocp master interface is used to get datas from system using ADMA2 procedure (direct access to the memory). This option is only available if generic parameter MADMA_EN is asserted to 1.
		0	The controller is slave on data transfers with system.
		1	Not available on this device.
19	DDR		Dual Data Rate mode. When this register is set, the controller uses both clock edge to emit or receive data. Odd bytes are transmitted on falling edges and even bytes are transmitted on rise edges. It only applies on Data bytes and CRC, Start, end bits and CRC status are kept full cycle. This bit field is only meaningful and active for even clock divider ratio of SD_SYSCTL[CLKD], it is insensitive to SD_HCTL[HSPE] setting
		0	Standard modeData are transmitted on a single edge.
		1	Data Bytes and CRC are transmitted on both edges.

Table 17-24. Configuration Register (SD_CON) Field Descriptions (continued)

Bit	Field	Value	Description
18	BOOT_CF0		Boot Status Supported. This register is set when the CMD line needs to be forced to 0 for a boot sequence. CMD line is driven to 0 after writing in SD_CMD. The line is released when this bit field is de-asserted and aborts data transfer in case of a pending transaction.
		Read 0	CMD line not forced.
		Read 1	CMD line is released when it was previously forced to 0 by a boot sequence.
		Write 0	CMD line forced to 0 is enabled.
		Write 1	CMD line forced to 0 is enabled and will be active after writing into SD_CMD register.
17	BOOT_ACK		Book acknowledge received. When this bit is set the controller should receive a boot status on DAT0 line after next command issued. If no status is received a data timeout will be generated.
		0	No acknowledge to be received.
		1	A boot status will be received on DAT0 line after issuing a command.
16	CLKEXTFREE		External clock free running. This register is used to maintain card clock out of transfer transaction to enable slave module (for example to generate a synchronous interrupt on mmc_dat[1]). The Clock will be maintain only if SD_SYSCTL[2] CEN bit is set.
		0	External card clock is cut off outside active transaction period.
		1	External card clock is maintain even out of active transaction period only if SD_SYSCTL[2] CEN bit is set.
15	PADEN		Control power for MMC lines. This register is only useful when MMC PADs contain power saving mechanism to minimize its leakage power. It works as a GPIO that directly control the ACTIVE pin of PADs. Excepted for mmc_dat[1] , the signal is also combine outside the module with the dedicated power control SD_CON[11] CTPL bit.
		0	ADPIDLE module pin is not forced, it is automatically generated by the MMC fsms.
		1	ADPIDLE module pin is forced to active state
14-13	Reserved	0	Any writes to these bits will result in 0.
12	CEATA		CE-ATA control mode (MMC cards compliant with CE-ATA). This bit selects the active level of the out-of-band interrupt coming from MMC cards. The usage of the Out-of-Band signal (OBI) is not supported.
		0	Standard MMC/SD/SDIO mode.
		1	CE-ATA mode. Next commands are considered as CE-ATA commands.
11	CTPL		Control Power for mmc_dat[1] line (SD cards). By default, this bit is cleared to 0 and the host controller automatically disables all the input buffers outside of a transaction to minimize the leakage current.
			SDIO cards. When this bit is set to 1, the host controller automatically disables all the input buffers except the buffer of mmc_dat[1] outside of a transaction in order to detect asynchronous card interrupt on mmc_dat[1] line and minimize the leakage current of the buffers.
		0	Disable all the input buffers outside of a transaction.
		1	Disable all the input buffers except the buffer of mmc_dat[1] outside of a transaction.
10-9	DVAL		Debounce filter value (all cards). This register is used to define a debounce period to filter the card detect input signal (SDCD). The usage of the card detect input signal (SDCD) is optional and depends on the system integration and the type of the connector housing that accommodates the card.
		0	33 us debounce period
		1h	231 us debounce period
		2h	1 ms debounce period
		3h	8.4 ms debounce period
8	WPP		Write protect polarity (SD and SDIO cards only). This bit selects the active level of the write protect input signal (SDWP). The usage of the write protect input signal (SDWP) is optional and depends on the system integration and the type of the connector housing that accommodates the card.
		0	Active high level
		1	Active low level

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Table 17-24. Configuration Register (SD_CON) Field Descriptions (continued)

Bit	Field	Value	Description
7	CDP		Card detect polarity (all cards). This bit selects the active level of the write protect input signal (SDWP). The usage of the write protect input signal (SDWP) is optional and depends on the system integration and the type of the connector housing that accommodates the card.
		0	Active high level
		1	Active low level
6	MIT		MMC interrupt command (MMC cards only). This bit must be set to 1, when the next write access to the command register (SD_CMD) is for writing a MMC interrupt command (CMD40) requiring the command timeout detection to be disabled for the command response.
		0	Command timeout enabled.
		1	Command timeout disabled.
5	DW8		8-bit mode MMC select (MMC cards only). For SD/SDIO cards, this bit must be cleared to 0. For MMC card, this bit must be set following a valid SWITCH command (CMD6) with the correct value and extend CSD index written in the argument. Prior to this command, the MMC card configuration register (CSD and EXT_CSD) must be verified for compliancy with MMC standard specification.
		0	1-bit or 4-bit data width
		1	8-bit data width
4	MODE		Mode select (all cards). This bit selects the functional mode.
		0	Functional mode. Transfers to the MMC/SD/SDIO cards follow the card protocol. The MMC clock is enabled. MMC/SD transfers are operated under the control of the SD_CMD register.
		1	SYSTEST mode. SYSTEST mode. The signal pins are configured as general-purpose input/output and the 1024-byte buffer is configured as a stack memory accessible only by the local host or system DMA. The pins retain their default type (input, output or in-out). SYSTEST mode is operated under the control of the SYSTEST register.
3	STR		Stream command (MMC cards only). This bit must be set to 1 only for the stream data transfers (read or write) of the adtc commands. Stream read is a class 1 command (CMD11READ_DAT_UNTIL_STOP). Stream write is a class 3 command (CMD20WRITE_DAT_UNTIL_STOP).
		0	Block oriented data transfer
		1	Stream oriented data transfer
2	HR		Broadcast host response (MMC cards only). This register is used to force the host to generate a 48-bit response for bc command type. It can be used to terminate the interrupt mode by generating a CMD40 response by the core. In order to have the host response to be generated in open drain mode, the register SD_CON[OD] must be set to 1. When SD_CON[12] CEATA bit is set to 1 and SD_ARG cleared to 0, when writing 0000 0000h into SD_CMD register, the host controller performs a 'command completion signal disable' token (i.e., mmc_cmd line held to 0 during 47 cycles followed by a 1).
		0	The host does not generate a 48-bit response instead of a command.
		1	The host generates a 48-bit response instead of a command or a command completion signal disable token.
1	INIT		Send initialization stream (all cards). When this bit is set to 1, and the card is idle, an initialization sequence is sent to the card. An initialization sequence consists of setting the mmc_cmd line to 1 during 80 clock cycles. The initialization sequence is mandatory - but it is not required to do it through this bit - this bit makes it easier. Clock divider (SD_SYSCTL[15:6] CLKD bits) should be set to ensure that 80 clock periods are greater than 1ms. Notein this mode, there is no command sent to the card and no response is expected. A command complete interrupt will be generated once the initialization sequence is completed. SD_STAT[0] CC bit can be polled.
		0	The host does not send an initialization sequence
		1	The host sends an initialization sequence
0	OD		Card open drain mode (MMC cards only). This bit must be set to 1 for MMC card commands 1, 2, 3 and 40, and if the MMC card bus is operating in open-drain mode during the response phase to the command sent. Typically, during card identification mode when the card is either in idle, ready or ident state. It is also necessary to set this bit to 1, for a broadcast host response (see Broadcast host response register SD_CON[2] HR bit)
		0	No open drain
		1	Open drain or broadcast host response

17.5.9 Power Counter Register (SD_PWCNT)

This register is used to program a mmc counter to delay command transfers after activating the PAD power, this value depends on PAD characteristics and voltage. The power counter register (SD_PWCNT) is shown in Figure 17-45 and described in Table 17-25.

Figure 17-45. Power Counter Register (SD_PWCNT)

31–16	15–0
Reserved	PWRCNT
R-0	R/W-0

LEGENDR/W = Read/Write; R = Read only; -*n* = value after reset

Table 17-25. Power Counter Register (SD_PWCNT) Field Descriptions

Bit	Field	Value	Description
31-16	Reserved	0	These bits are initialized to zero, and writes to them are ignored. Reads return 0.
15-0	PWRCNT		Power counter register. This register is used to introduce a delay between the PAD ACTIVE pin assertion and the command issued.
		0	No additional delay added
		1h	TCF delay (card clock period)
		2h	TCF x 2 delay (card clock period)
		FFFEh	TCF x 65534 delay (card clock period)
		FFFFh	TCF x 65535 delay (card clock period)

17.5.10 SDMA System Address (SD_SDMASA)

This register is used to program a mmc counter to delay command transfers after activating the PAD power. This value depends on PAD characteristics and voltage. The SDMA System address (SD_SDMASA) is shown in Figure 17-42 and described in Table 17-22.

Figure 17-46. Card Status Response Error (SD_SDMASA)

31–0
SDMA_SYSADDR
R-0

LEGENDR/W = Read/Write; R = Read only; -*n* = value after reset

Table 17-26. Card Status Response Error (SD_SDMASA) Field Descriptions

Bit	Field	Value	Description
31-0	SDMA_SYSADDR		This register contains the system memory address for a SDMA transfer. When the Host Controller stops a SDMA transfer, this register shall point to the system address of the next contiguous data position. It can be accessed only if no transaction is executing (i.e., after a transaction has stopped). Read operations during transfers may return an invalid value. The Host Driver shall initialize this register before starting a SDMA transaction. After SDMA has stopped, the next system address of the next contiguous data position can be read from this register. The SDMA transfer waits at the every boundary specified by the Host SDMA Buffer Boundary in the Block Size register. The Host Controller generates DMA Interrupt to request the Host Driver to update this register. The Host Driver sets the next system address of the next data position to this register. When the most upper byte of this register (003h) is written, the Host Controller restarts the SDMA transfer. When restarting SDMA by the Resume command or by setting Continue Request in the Block Gap Control register, the Host Controller shall start at the next contiguous address stored here in the SDMA System Address register. ADMA does not use this register.

17.5.11 Transfer Length Configuration Register (SD_BLK)

This register shall be used for any card. SD_BLK[BLEN] is the block size register. SD_BLK[NBLK] is the block count register.

The transfer length configuration register (SD_BLK) is shown in Figure 17-47 and described in Table 17-27.

Figure 17-47. Transfer Length Configuration Register (SD_BLK)

31–16	15–12	11–0
NBLK	Reserved	BLEN
R/W-0	R-0	R/W-0

LEGENDR/W = Read/Write; R = Read only; -*n* = value after reset

Table 17-27. Transfer Length Configuration Register (SD_BLK) Field Descriptions

Bit	Field	Value	Description
31-16	NBLK		Blocks count for current transfer. This register is enabled when Block count Enable (SD_CMD[1] BCE bit) is set to 1 and is valid only for multiple block transfers. Setting the block count to 0 results no data blocks being transferred. NoteThe host controller decrements the block count after each block transfer and stops when the count reaches zero. This register can be accessed only if no transaction is executing (i.e., after a transaction has stopped). Read operations during transfers may return an invalid value and write operation will be ignored. In suspend context, the number of blocks yet to be transferred can be determined by reading this register. When restoring transfer context prior to issuing a Resume command, The local host shall restore the previously saved block count.
		0	Stop count
		1h	1 block
		2h	2 blocks
		FFFFh	65535 blocks
15-12	Reserved	0	Reserved bit field. Do not write any value.
11-0	BLEN		Transfer block size. This register specifies the block size for block data transfers. Read operations during transfers may return an invalid value, and write operations are ignored. When a CMD12 command is issued to stop the transfer, a read of the BLEN field after transfer completion (SD_STAT[1] TC bit set to 1) will not return the true byte number of data length while the stop occurs but the value written in this register before transfer is launched.
		0	No data transfer
		1h	1 byte block length
		2h	2 bytes block length
		3h	3 bytes block length
		1FFh	511 bytes block length
		200h	512 bytes block length
		7FFh	2047 bytes block length
		800h	2048 bytes block length

17.5.12 Command Argument Register (SD_ARG)

This register contains command argument specified as bit 39-8 of Command-Format. These registers must be initialized prior to sending the command itself to the card (write action into the register SD_CMD register). Only exception is for a command index specifying stuff bits in arguments, making a write unnecessary.

The command argument register (SD_ARG) is shown in Figure 17-48 and described in Table 17-28.

17.5.13 Command and Transfer Mode Register (SD_CMD)

- SD_CMD[31:16] = the command register
- SD_CMD[15:0] = the transfer mode

This register configures the data and command transfers. A write into the most significant byte send the command. A write into SD_CMD[15:0] registers during data transfer has no effect.

This register can be used for any card.

NOTE: In SYSTEST mode, a write into SD_CMD register will not start a transfer.

The command and transfer mode register (SD_CMD) is shown in Figure 17-49 and described in Table 17-29.

Table 17-29. Command and Transfer Mode Register (SD_CMD) Field Descriptions (continued)

Bit	Field	Value	Description
		2Eh	CMD46 or ACMD46
		2Fh	CMD47 or ACMD47
		30h	CMD48 or ACMD48
		31h	CMD49 or ACMD49
		32h	CMD50 or ACMD5
		33h	CMD51 or ACMD5
		34h	CMD52 or ACMD5
		35h	CMD53 or ACMD5
		36h	CMD54 or ACMD5
		37h	CMD55 or ACMD5
		38h	CMD56 or ACMD5
		39h	CMD57 or ACMD5
		3Ah	CMD58 or ACMD5
		3Bh	CMD59 or ACMD5
		3Ch	CMD60 or ACMD60
		3Dh	CMD61 or ACMD61
		3Eh	CMD62 or ACMD62
		3Fh	CMD63 or ACMD63
23-22	CMD_TYPE		Command type. This register specifies three types of special commandSuspend, Resume and Abort. These bits shall be cleared to 0b00 for all other commands.
		0	Others commands
		1h	Upon CMD52 "Bus Suspend" operation
		2h	Upon CMD52 "Function Select" operation
		3h	Upon CMD12 or CMD52 "I/O Abort" command
21	DP		Data present select. This register indicates that data is present and mmc_dat line shall be used. It must be cleared to 0 in the following conditions: • Command using only mmc_cmd line • Command with no data transfer but using busy signal on mmc_dat0 • Resume command
		0	Command with no data transfer
		1	Command with data transfer
20	CICE		Command Index check enable. This bit must be set to 1 to enable index check on command response to compare the index field in the response against the index of the command. If the index is not the same in the response as in the command, it is reported as a command index error (SD_STAT[19] CIE bit set to1) NoteThe CICE bit cannot be configured for an Auto CMD12, then index check is automatically checked when this command is issued.
		0	Index check disable
		1	Index check enable
19	CCCE		Command CRC check enable. This bit must be set to 1 to enable CRC7 check on command response to protect the response against transmission errors on the bus. If an error is detected, it is reported as a command CRC error (SD_STAT[17] CCRC bit set to 1). NoteThe CCCE bit cannot be configured for an Auto CMD12, and then CRC check is automatically checked when this command is issued.
		0	CRC7 check disable
		1	CRC7 check enable
18	Reserved	0	Reserved bit field. Do not write any value.
17-16	RSP_TYPE		Response type. This bits defines the response type of the command.
		0	No response
		1h	Response Length 136 bits
		2h	Response Length 48 bits
		3h	Response Length 48 bits with busy after response

Table 17-29. Command and Transfer Mode Register (SD_CMD) Field Descriptions (continued)

Bit	Field	Value	Description
15-6	Reserved	0	Reserved bit field. Do not write any value.
5	MSBS		Multi/Single block select. This bit must be set to 1 for data transfer in case of multi block command. For any others command this bit shall be cleared to 0.
		0	Single block. If this bit is 0, it is not necessary to set the register SD_BLK[31:16] NBLK bits.
		1	Multi block. When Block Count is disabled (SD_CMD[1] BCE bit is cleared to 0) in Multiple block transfers (SD_CMD[5] MSBS bit is set to 1), the module can perform infinite transfer.
4	DDIR		Data transfer Direction. Select This bit defines either data transfer will be a read or a write.
		0	Data Write (host to card)
		1	Data Read (card to host)
3	Reserved	0	Reserved bit field. Do not write any value.
2	ACEN		Auto CMD12 Enable (SD cards only). When this bit is set to 1, the host controller issues a CMD12 automatically after the transfer completion of the last block. The Host Driver shall not set this bit to issue commands that do not require CMD12 to stop data transfer. In particular, secure commands do not require CMD12. For CE-ATA commands (SD_CON[12] CEATA bit set to 1), auto CMD12 is useless; therefore when this bit is set the mechanism to detect command completion signal, named CCS, interrupt is activated.
		0	Auto CMD12 disable
		1	Auto CMD12 enable or CCS detection enabled.
1	BCE		Block Count Enable (Multiple block transfers only). This bit is used to enable the block count register (SD_BLK[31:16] NBLK bits). When Block Count is disabled (SD_CMD[1] BCE bit is cleared to 0) in Multiple block transfers (SD_CMD[5] MSBS bits is set to 1), the module can perform infinite transfer.
		0	Block count disabled for infinite transfer.
		1	Block count enabled for multiple block transfer with known number of blocks
0	DE		DMA Enable. This bit is used to enable DMA mode for host data access.
		0	DMA mode disable
		1	DMA mode enable

17.5.18 Data Register (SD_DATA)

This register is the 32-bit entry point of the buffer for read or write data transfers. The buffer size is 32bitsx256(1024 bytes). Bytes within a word are stored and read in little endian format. This buffer can be used as two 512 byte buffers to transfer data efficiently without reducing the throughput.

Sequential and contiguous access is necessary to increment the pointer correctly. Random or skipped access is not allowed. In little endian, if the local host accesses this register byte-wise or 16bit-wise, the least significant byte (bits [7:0]) must always be written/read first. The update of the buffer address is done on the most significant byte write for full 32-bit DATA register or on the most significant byte of the last word of block transfer.

Example 1Byte or 16-bit access

- Mbyteen[3:0]=0001 (1-byte) => Mbyteen[3:0]=0010 (1-byte) => Mbyteen[3:0]=1100 (2-bytes) OK
- Mbyteen[3:0]=0001 (1-byte) => Mbyteen[3:0]=0010 (1-byte) => Mbyteen[3:0]=0100 (1-byte) OK
- Mbyteen[3:0]=0001 (1-byte) => Mbyteen[3:0]=0010 (1-byte) => Mbyteen[3:0]=1000 (1-byte) Bad

The data register (SD_DATA) is shown in Figure 17-54 and described in Table 17-34.

Figure 17-54. Data Register (SD_DATA)

31	0
DATA	
R/W-0	

LEGENDR/W = Read/Write; R = Read only; -*n* = value after reset

Table 17-34. Data Register (SD_DATA) Field Descriptions

Bit	Field	Value	Description
31-0	DATA		Data register [31:0]. In functional mode (SD_CON[4] MODE bit set to the default value 0): A read access to this register is allowed only when the buffer read enable status is set to 1 (SD_PSTATE[11] BRE bit), otherwise a bad access (SD_STAT[29] BADA bit) is signaled. A write access to this register is allowed only when the buffer write enable status is set to 1 (SD_PSTATE[10] BWE bit), otherwise a bad access (SD_STAT[29] BADA bit) is signaled and the data is not written.

17.5.19 Present State Register (SD_PSTATE)

The Host can get the status of the Host controller from this 32-bit read only register. The present state register (SD_PSTATE) is shown in Figure 17-55 and described in Table 17-35.

Figure 17-55. Present State Register (SD_PSTATE)

31–25	24	23–20	19	18	17	16
Reserved	CLEV	DLEV	WP	CDPL	CSS	CINS
R-0	R-x	R-x	R-0	R-0	R-0	R-0

15–12	11	10	9	8	7–3	2	1	0
Reserved	BRE	BWE	RTA	WTA	Reserved	DLA	DATI	CMDI
R-0	R-0	R-0	R-0	R-0	R-0	R-0	R-0	R-0

LEGENDR/W = Read/Write; R = Read only; -*n* = value after reset

Table 17-35. Present State Register (SD_PSTATE) Field Descriptions

Bit	Field	Value	Description
31-25	Reserved	0	Reserved bit field. Do not write any value.
24	CLEV		mmc_cmd line signal level. This status is used to check the mmc_cmd line level to recover from errors, and for debugging. The value of this register after reset depends on the mmc_cmd line level at that time.
		Read 0	The mmc_cmd line level is 0.
		Read 1	The mmc_cmd line level is 1.
23-20	DLEV		mmc_dat[3:0] line signal level • mmc_dat3 => bit 23 • mmc_dat2 => bit 22 • mmc_dat1 => bit 21 • mmc_dat0 => bit 20 This status is used to check mmc_dat line level to recover from errors, and for debugging. This is especially useful in detecting the busy signal level from mmc_dat0 . The value of these registers after reset depends on the mmc_dat lines level at that time.
19	WP		Write Protect. MMC/SD/SDIO1 only. SDIO cards only. This bit reflects the write protect input pin (SDWP) level. The value of this register after reset depends one the protect input pin (SDWP) level at that time.
		Read 0	If SD_CON[8] WPP is cleared to 0 (default), the card is write protected, otherwise the card is not write protected.
		Read 1	If SD_CON[8] WPP is cleared to 0 (default), the card is not write protected, otherwise the card is write protected.
18			Card Detect Pin Level. MMC/SD/SDIO1 only. SDIO cards only. This bit reflects the inverse value of the card detect input pin (SDCD). Debouncing is not performed on this bit and is valid only when Card State is stable. (SD_PSTATE[17] is set to 1). This bit must be debounced by software. The value of this register after reset depends on the card detect input pin (SDCD) level at that time.
		Read 0	The value of the card detect input pin (SDCD) is 1.
		Read 1	The value of the card detect input pin (SDCD) is 0.
17			Card State Stable. This bit is used for testing. It is set to 1 only when Card Detect Pin Level is stable (SD_PSTATE[18] CPDL). Debouncing is performed on the card detect input pin (SDCD) to detect card stability. This bit is not affected by software reset.
		Read 0	Reset or Debouncing.
		Read 1	Reset or Debouncing.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Table 17-35. Present State Register (SD_PSTATE) Field Descriptions (continued)

Bit	Field	Value	Description
16			Card inserted. This bit is the debounced value of the card detect input pin (SDCD). An inactive to active transition of the card detect input pin (SDCD) will generate a card insertion interrupt (SD_STAT[CINS]). A active to inactive transition of the card detect input pin (SDCD) will generate a card removal interrupt (SD_STAT[REM]). This bit is not affected by a software reset.
		Read 0	If SD_CON[CDP] is cleared to 0 (default), no card is detected. The card may have been removed from the card slot. If SD_CON[CDP] is set to 1, the card has been inserted.
		Read 1	If SD_CON[CDP] is cleared to 0 (default), the card has been inserted from the card slot. If SD_CON[CDP] is set to 1, no card is detected. The card may have been removed from the card slot.
15-12	Reserved	0	Reserved bit field. Do not write any value.
11	BRE		Buffer read enable. This bit is used for non-DMA read transfers. It indicates that a complete block specified by SD_BLK[10:0] BLEN bits has been written in the buffer and is ready to be read. It is cleared to 0 when the entire block is read from the buffer. It is set to 1 when a block data is ready in the buffer and generates the Buffer read ready status of interrupt (SD_STAT[5] BRR bit).
		Read 0	Read BLEN bytes disable
		Read 1	Read BLEN bytes enable. Readable data exists in the buffer.
10	BWE		Buffer Write enable. This status is used for non-DMA write transfers. It indicates if space is available for write data.
		Read 0	There is no room left in the buffer to write BLEN bytes of data.
		Read 1	There is enough space in the buffer to write BLEN bytes of data.
9	RTA		Read transfer active. This status is used for detecting completion of a read transfer. It is set to 1 after the end bit of read command or by activating a continue request (SD_HCTL[17] CR bit) following a stop at block gap request. This bit is cleared to 0 when all data have been read by the local host after last block or after a stop at block gap request.
		Read 0	No valid data on the mmc_dat lines.
		Read 1	Read data transfer on going.
8	WTA		Write transfer active. This status indicates a write transfer active. It is set to 1 after the end bit of write command or by activating a continue request (SD_HCTL[17] CR bit) following a stop at block gap request. This bit is cleared to 0 when CRC status has been received after last block or after a stop at block gap request.
		Read 0	No valid data on the mmc_dat lines.
		Read 1	Write data transfer on going.
7-3	Reserved	0	Reserved bit field. Do not write any value.
2	DLA		mmc_dat line active. This status bit indicates whether one of the mmc_dat lines is in use. In the case of read transactions (card to host)This bit is set to 1 after the end bit of read command or by activating continue request SD_HCTL[17] CR bit. This bit is cleared to 0 when the host controller received the end bit of the last data block or at the beginning of the read wait mode. In the case of write transactions (host to card)This bit is set to 1 after the end bit of write command or by activating continue request SD_HCTL[17] CR bit. This bit is cleared to 0 on the end of busy event for the last block; host controller must wait 8 clock cycles with line not busy to really consider not "busy state" or after the busy block as a result of a stop at gap request.
		Read 0	mmc_dat line inactive
		Read 1	mmc_dat line active
1	DATI		Command inhibit (mmc_dat). This status bit is generated if either mmc_dat line is active (SD_PSTATE[2] DLA bit) or Read transfer is active (SD_PSTATE[9] RTA bit) or when a command with busy is issued. This bit prevents the local host to issue a command. A change of this bit from 1 to 0 generates a transfer complete interrupt (SD_STAT[1] TC bit).
		Read 0	Issuing of command using the mmc_dat lines is allowed
		Read 1	Issuing of command using mmc_dat lines is not allowed

Copyright © 2011, Texas Instruments Incorporated

Table 17-35. Present State Register (SD_PSTATE) Field Descriptions (continued)

Bit	Field	Value	Description
0	CMDI		Command inhibit(mmc_cmd). This status bit indicates that the mmc_cmd line is in use. This bit is cleared to 0 when the most significant byte is written into the command register. This bit is not set when Auto CMD12 is transmitted. This bit is cleared to 0 in either the following cases: • After the end bit of the command response, excepted if there is a command conflict error (SD_STAT[17] CCRC bit or SD_STAT[18] CEB bit set to 1) or a Auto CMD12 is not executed (SD_AC12[0] ACNE bit). • After the end bit of the command without response (SD_CMD[17:16] RSP_TYPE bits set to "00"). In case of a command data error is detected (SD_STAT[19] CTO bit set to 1), this register is not automatically cleared.
		Read 0	Issuing of command using mmc_cmd line is allowed
		Read 1	Issuing of command using mmc_cmd line is not allowed

17.5.20 Control Register (SD_HCTL)

This register defines the host controls to set power, wake-up and transfer parameters.

- SD_HCTL[31:24] = Wake-up control
- SD_HCTL[23:16] = Block gap control
- SD_HCTL[15:8] = Power control
- SD_HCTL[7:0] = Host control

NOTE: If your device does not support MMC cards, then those bits in this register which are meant for MMC card use should be assumed to be reserved.

The control register (SD_HCTL) is shown in Figure 17-56 and described in Table 17-36.

Figure 17-56. Control Register (SD_HCTL)

Bit	Field	Value	Description
31-28	Reserved	0	Reserved bit field. Do not write any value.
27	OBWE		Wake-up event enable for 'out-of-band' Interrupt. This bit enables wake-up events for 'out-of-band' assertion. Wake-up is generated if the wake-up feature is enabled (SD_SYSCONFIG[2] ENAWAKEUP bit). The write to this register is ignored when SD_CON[14] OBIE bit is not set.
		0	Disable wake-up on 'out-of-band' Interrupt
		1	Enable wake-up on 'out-of-band' Interrupt
26	REM		Wake-up event enable on SD card removal. This bit enables wake-up events for card removal assertion. Wake-up is generated if the wake-up feature is enabled (SD_SYSCONFIG[2] ENAWAKEUP bit).
		0	Disable wake-up on card removal
		1	Enable wake-up on card removal
25	INS		Wake-up event enable on SD card insertion This bit enables wake-up events for card insertion assertion. Wake-up is generated if the wake-up feature is enabled (SD_SYSCONFIG[2] ENAWAKEUP bit).
		0	Disable wake-up on card insertion
		1	Enable wake-up on card insertion
24	IWE		Wake-up event enable on SD card interrupt. This bit enables wake-up events for card interrupt assertion. Wake-up is generated if the wake-up feature is enabled (SD_SYSCONFIG[2] ENAWAKEUP bit) and enable status bit is set (SD_IE[8] CIRQ_ENABLE bit).
		0	Disable wake-up on card interrupt
		1	Enable wake-up on card interrupt
23-20	Reserved	0	Reserved bit field. Do not write any value.
19	IBG		Interrupt block at gap. This bit is valid only in 4-bit mode of SDIO card to enable interrupt detection in the interrupt cycle at block gap for a multiple block transfer. For MMC cards and for SD card this bit should be cleared to 0.
		0	Disable interrupt detection at the block gap in 4-bit mode
		1	Enable interrupt detection at the block gap in 4-bit mode

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Table 17-36. Control Register (SD_HCTL) Field Descriptions (continued)

Bit	Field	Value	Description
18	RWC		Read wait control. The read wait function is optional only for SDIO cards. If the card supports read wait, this bit must be enabled, then requesting a stop at block gap (SD_HCTL[16] SBGR bit) generates a read wait period after the current end of block. Be careful, if read wait is not supported it may cause a conflict on mmc_dat line.
		0	Disable read wait control. Suspend/resume cannot be supported.
		1	Enable read wait control
17	CR		Continue request. This bit is used to restart a transaction that was stopped by requesting a stop at block gap (SD_HCTL[16] SBGR bit). Set this bit to 1 restarts the transfer. The bit is automatically cleared to 0 by the host controller when transfer has restarted, that is, mmc_dat line is active (SD_PSTATE[2] DLA bit) or transferring data (SD_PSTATE[8] WTA bit). The Stop at block gap request must be disabled (SD_HCTL[16] SBGR bit =0) before setting this bit.
		0	No affect
		1	Transfer restart
16	SBGR		Stop at block gap request. This bit is used to stop executing a transaction at the next block gap. The transfer can restart with a continue request (SD_HCTL[17] CR bit) or during a suspend/resume sequence. In case of read transfer, the card must support read wait control. In case of write transfer, the host driver shall set this bit after all block data written. Until the transfer completion (SD_STAT[1] TC bit set to 1), the host driver shall leave this bit set to 1.If this bit is set, the local host shall not write to the data register (SD_DATA).
		0	Transfer mode
		1	Stop at block gap
15-12	Reserved	0	Reserved bit field. Do not write any value.
11-9	SDVS		SD bus voltage select (All cards). The host driver should set these bits to select the voltage level for the card according to the voltage supported by the system (SD_CAPA[26] VS18 bit, SD_CAPA[25] VS30 bit, SD_CAPA[24] VS33 bit) before starting a transfer.
			MMCHS2. This field must be set to 5h.
			MMCHS3. This field must be set to 5h.
		5h	1.8 V (Typical)
		6h	3.0 V (Typical)
		7h	3.3 V (Typical)
8	SDBP		SD bus power. Before setting this bit, the host driver shall select the SD bus voltage (SD_HCTL[11:9] SDVS bits). If the host controller detects the No card state, this bit is automatically cleared to 0. If the module is power off, a write in the command register (SD_CMD) will not start the transfer. A write to this bit has no effect if the selected SD bus voltage is not supported according to capability register (SD_CAPA[VS*]).
		0	Power off
		1	Power on
7	CDSS		Card Detect Signal Selection. This bit selects source for the card detection. When the source for the card detection is switched, the interrupt should be disabled during the switching period by clearing the Interrupt Status/Signal Enable register in order to mask unexpected interrupt being caused by the glitch. The Interrupt Status/Signal Enable should be disabled during over the period of debouncing.
		0	SDCD# is selected (for normal use).
		1	The Card Detect Test Level is selected (for test purposes).
6	CDTL		Card Detect Test Level. This bit is enabled while the Card Detect Signal Selection is set to 1 and it indicates card inserted or not.
		0	No card
		1	Card inserted.
5	Reserved	0	Reserved bit field. Do not write any value.

Table 17-36. Control Register (SD_HCTL) Field Descriptions (continued)

Bit	Field	Value	Description
4-3	DMAS		DMA Select. One of the supported DMA modes can be selected. The host driver shall check support of DMA modes by referencing the Capabilities register. Use of selected DMA is determined by DMA Enable of the Transfer Mode register. This register is only meaningful when MADMA_EN is set to 1. When MADMA_EN is cleared to 0 the bit field is read only and returned value is 0.
		0-1h	Reserved
		2h	32-bit Address ADMA2 is selected.
		3h	Reserved
2	HSPE		High Speed Enable. Before setting this bit, the Host Driver shall check the High Speed Support in the Capabilities register. If this bit is cleared to 0 (default), the Host Controller outputs CMD line and DAT lines at the falling edge of the SD Clock. If this bit is set to 1, the Host Controller outputs CMD line and DAT lines at the rising edge of the SD Clock. This bit shall not be set when dual data rate mode is activated in SD_CON[DDR].
		0	Normal speed mode
		1	High speed mode
1	DTW		Data transfer width. This bit must be set following a valid SET_BUS_WIDTH command (ACMD6) with the value written in bit 1 of the argument. Prior to this command, the SD card configuration register (SCR) must be verified for the supported bus width by the SD card.
		0	1-bit Data width (mmc_dat0 used)
		1	4-bit Data width (mmc_dat[3:0] used)
0	Reserved	0	Reserved bit field. Do not write any value.

17.5.21 SD System Control Register (SD_SYSCTL)

This register defines the system controls to set software resets, clock frequency management and data timeout.

- SD_SYSCTL[31:24] = Software resets
- SD_SYSCTL[23:16] = Timeout control
- SD_SYSCTL[15:0] = Clock control

The SD system control register (SD_SYSCTL) is shown in Figure 17-57 and described in Table 17-37.

Figure 17-57. SD System Control Register (SD_SYSCTL)

31–27	26	25	24	23–20	19–16
Reserved	SRD	SRC	SRA	Reserved	DTO
R-0	R/W-0	R/W-0	R/W-0	R-0	R/W-0

15–6	5–3	2	1	0
CLKD	Reserved	CEN	ICS	ICE
R/W-0	R-0	R/W-0	R-0	R/W-0

LEGENDR/W = Read/Write; R = Read only; -*n* = value after reset

Table 17-37. SD System Control Register (SD_SYSCTL) Field Descriptions

Bit	Field	Value	Description
31-27	Reserved	0	Reserved bit field. Do not write any value.
26	SRD		Software reset for mmc_dat line. This bit is set to 1 for reset and released to 0 when completed. mmc_dat finite state machine in both clock domain are also reset. These registers are cleared by the SD_SYSCTL[26] SRD bit: • SD_DATA • SD_PSTATEBRE, BWE, RTA, WTA, DLA and DATI • SD_HCTLSBGR and CR • SD_STATBRR, BWR, BGE and TC Interconnect and MMC buffer data management is reinitialized. **Note**If a soft reset is issued when an interrupt is asserted, data may be lost.
		0	Reset completed
		1	Software reset for mmc_dat line
25	SRC		Software reset for mmc_cmd line. This bit is set to 1 for reset and released to 0 when completed. mmc_cmd finite state machine in both clock domain are also reset. These registers are cleared by the SD_SYSCTL[25] SRC bit: • SD_PSTATECMDI • SD_STATCC Interconnect and MMC command status management is reinitialized. **Note**If a soft reset is issued when an interrupt is asserted, data may be lost.
		0	Reset completed
		1	Software reset for mmc_cmd line
24	SRA		Software reset for all. This bit is set to 1 for reset , and released to 0 when completed. This reset affects the entire host controller except for the card detection circuit and capabilities registers.
		0	Reset completed
		1	Software reset for all the design
23-20	Reserved	0	Reserved bit field. Do not write any value.

DRAFT ONLY

Table 17-37. SD System Control Register (SD_SYSCTL) Field Descriptions (continued)

Bit	Field	Value	Description
19-16	DTO		Data timeout counter value and busy timeout. This value determines the interval by which mmc_dat lines timeouts are detected. The host driver needs to set this bit field based on: • The maximum read access time (NAC) (Refer to the SD Specification Part1 Physical Layer) • The data read access time values (TAAC and NSAC) in the card specific data register (CSD) of the card • The timeout clock base frequency (SD_CAPA[5:0] TCF bits) If the card does not respond within the specified number of cycles, a data timeout error occurs (SD_STAT[20] DTO bit). The SD_SYSCTL[19,16] DTO bit field is also used to check busy duration, to generate busy timeout for commands with busy response or for busy programming during a write command. Timeout on CRC status is generated if no CRC token is present after a block write.
		0	TCF x 2^13
		1h	TCF x 2^14
		Eh	TCF x 2^27
		Fh	Reserved
15-6	CLKD		Clock frequency select. These bits define the ratio between a reference clock frequency (system dependant) and the output clock frequency on the mmc_clk pin of either the memory card (MMC, SD, or SDIO).
		0	Clock Ref bypass
		1h	Clock Ref bypass
		2h	Clock Ref / 2
		3h	Clock Ref / 3
		3FFh	Clock Ref / 1023
5-3	Reserved	0	Reserved bit field. Do not write any value.
2	CEN		Clock enable. This bit controls if the clock is provided to the card or not.
		0	The clock is not provided to the card . Clock frequency can be changed .
		1	The clock is provided to the card and can be automatically gated when SD_SYSCONFIG[0] AUTOIDLE bit is set to 1 (default value) . The host driver shall wait to set this bit to 1 until the Internal clock is stable (SD_SYSCTL[1] ICS bit).
1	ICS		Internal clock stable (status)This bit indicates either the internal clock is stable or not.
		0	The internal clock is not stable.
		1	The internal clock is stable after enabling the clock (SD_SYSCTL[0] ICE bit) or after changing the clock ratio (SD_SYSCTL[15:6] CLKD bits).
0	ICE		Internal clock enable. This register controls the internal clock activity. In very low power state, the internal clock is stopped. NoteThe activity of the debounce clock (used for wake-up events) and the interface clock (used for reads and writes to the module register map) are not affected by this register.
		0	The internal clock is stopped (very low power state).
		1	The internal clock oscillates and can be automatically gated when SD_SYSCONFIG[0] AUTOIDLE bit is set to 1 (default value).

17.5.22 Interrupt Status Register (SD_STAT)

The interrupt status regroups all the status of the module internal events that can generate an interrupt.

- SD_STAT[31:16] = Error Interrupt Status
- SD_STAT[15:0] = Normal Interrupt Status

The error bits are located in the upper 16 bits of the SD_STAT register. All bits are cleared by writing a 1 to them. Additionally, bits 15 and 8 serve as special error bits. These cannot be cleared by writing a 1 to them. Bit 15 (ERRI) is automatically cleared when the error causing to ERRI to be set is handled. (that is, when bits 31:16 are cleared, bit 15 will be automatically cleared). Bit 8 (CIRQ) is cleared by writing a 0 to SD_IE[8] (masking the interrupt) and servicing the interrupt.

The interrupt status register (SD_STAT) is shown in Figure 17-58 and described in Table 17-38.

Figure 17-58. Interrupt Status Register (SD_STAT)

31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved		BADA	CERR	Reserved		ADMAE	ACE	Rsvd	DEB	DCRC	DTO	CIE	CEB	CCRC	CTO
R-0		R/W-0	R/W-0	R-0		R/W-0	R/W-0	R-0	R/W-0	R/W-0	R/W-0	R/W-0	R/W-0	R/W-0	R/W-0

15	14	10	9	8	7	6	5	4	3	2	1	0
ERRI	Reserved	BSR	OBI	CIRQ	CREM	CINS	BRR	BWR	DMA	BGE	TC	CC
R-0	R-0	R/W-0	R-0	R-0	R/W-0	R/W-0	R/W-0	R/W-0	R/W-0	R/W-0	R/W-0	R/W-0

LEGENDR/W = Read/Write; R = Read only; -*n* = value after reset

Table 17-38. Interrupt Status Register (SD_STAT) Field Descriptions

Bit	Field	Value	Description
31-30	Reserved	0	Reserved bit field. Do not write any value
29	BADA		Bad access to data space. This bit is set automatically to indicate a bad access to buffer when not allowed: • During a read access to the data register (SD_DATA) while buffer reads are not allowed (SD_PSTATE[11] BRE bit =0) • During a write access to the data register (SD_DATA) while buffer writes are not allowed (SD_PSTATE[10] BWE bit=0)
		Read 0	No interrupt
		Write 0	Status bit unchanged
		Read 1	Bad access
		Write 1	Status is cleared.
28	CERR		Card error. This bit is set automatically when there is at least one error in a response of type R1, R1b, R6, R5 or R5b. Only bits referenced as type E (error) in status field in the response can set a card status error. An error bit in the response is flagged only if corresponding bit in card status response error SD_CSRE in set. There is no card error detection for autoCMD12 command. The host driver shall read SD_RSP76 register to detect error bits in the command response.
		Read 0	No error
		Write 0	Status bit unchanged
		Read 1	Card error
		Write 1	Status is cleared.
27-26	Reserved	0	Reserved bit field. Do not write any value

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Table 17-38. Interrupt Status Register (SD_STAT) Field Descriptions (continued)

Bit	Field	Value	Description
25	ADMAE		ADMA Error. This bit is set when the Host Controller detects errors during ADMA based data transfer. The state of the ADMA at an error occurrence is saved in the ADMA Error Status Register. In addition, the Host Controller generates this interrupt when it detects invalid descriptor data (Valid=0) at the ST_FDS state. ADMA Error State in the ADMA Error Status indicates that an error occurs in ST_FDS state. The Host Driver may find that Valid bit is not set at the error descriptor.
		Read 0	No interrupt
		Write 0	Status bit unchanged
		Read 1	ADMA error
		Write 1	Status is cleared.
24	ACE		Auto CMD12 error. This bit is set automatically when one of the bits in Auto CMD12 Error status register has changed from 0 to 1.
		Read 0	No error
		Write 0	Status bit unchanged
		Read 1	AutoCMD12 error
		Write 1	Status is cleared.
23	Reserved	0	Reserved bit field. Do not write any value
22	DEB		Data End Bit error. This bit is set automatically when detecting a 0 at the end bit position of read data on mmc_dat line or at the end position of the CRC status in write mode.
		Read 0	No error
		Write 0	Status bit unchanged
		Read 1	Data end bit error
		Write 1	Status is cleared.
21	DCRC		Data CRC Error. This bit is set automatically when there is a CRC16 error in the data phase response following a block read command or if there is a 3-bit CRC status different of a position "010" token during a block write command.
		Read 0	No error
		Write 0	Status bit unchanged
		Read 1	Data CRC error
		Write 1	Status is cleared.
20	DTO		Data timeout error. This bit is set automatically according to the following conditions: • Busy timeout for R1b, R5b response type • Busy timeout after write CRC status • Write CRC status timeout • Read data timeout
		Read 0	No error
		Write 0	Status bit unchanged
		Read 1	Time out
		Write 1	Status is cleared.
19	CIE		Command index error. This bit is set automatically when response index differs from corresponding command index previously emitted. It depends on the enable bit (SD_CMD[20] CICE).
		Read 0	No error
		Write 0	Status bit unchanged
		Read 1	Command index error
		Write 1	Status is cleared.

Table 17-38. Interrupt Status Register (SD_STAT) Field Descriptions (continued)

Bit	Field	Value	Description
18	CEB		Command end bit error. This bit is set automatically when detecting a 0 at the end bit position of a command response.
		Read 0	No error
		Write 0	Status bit unchanged
		Read 1	Command end bit error
		Write 1	Status is cleared.
17	CCRC		Command CRC error. This bit is set automatically when there is a CRC7 error in the command response depending on the enable bit (SD_CMD[19] CCCE).
		Read 0	No error
		Write 0	Status bit unchanged
		Read 1	Command CRC error
		Write 1	Status is cleared.
16	CTO		Command timeout error. This bit is set automatically when no response is received within 64 clock cycles from the end bit of the command.
			For commands that reply within 5 clock cycles - the timeout is still detected at 64 clock cycles.
		Read 0	No error
		Write 0	Status bit unchanged
		Read 1	Time Out
		Write 1	Status is cleared.
15	ERRI		Error interrupt. If any of the bits in the Error Interrupt Status register (SD_STAT[31:16]) are set, then this bit is set to 1. Therefore the host driver can efficiently test for an error by checking this bit first.
			Writes to this bit are ignored.
		Read 0	No interrupt
		Read 1	Error interrupt event(s) occurred
14-11	Reserved	0	Reserved bit field. Do not write any value
10	BSR		Boot Status Received Interrupt. This bit is set automatically when SD_CON[BOOT] is set 1 or 2 and a boot status is received on DAT[0] line. This interrupt is only useful for MMC card.
		Read 0	No interrupt
		Write 0	Status bit unchanged
		Read 1	Boot Status Received Interrupt occurred.
		Write 1	Status is cleared.
9	OBI		Out-of-band interrupt (This interrupt is only useful for MMC card). This bit is set automatically when SD_CON[14] OBIE bit is set and an out-of-band interrupt occurs on OBI pin.
			The interrupt detection depends on polarity controlled by SD_CON[13] OBIP bit.
			The out-of-band interrupt signal is a system specific feature for future use, this signal is not required for existing specification implementation.
		Read 0	No out-of-band interrupt
		Write 0	Status bit unchanged
		Read 1	Interrupt out-of-band occurs
		Write 1	Status is cleared.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Table 17-38. Interrupt Status Register (SD_STAT) Field Descriptions (continued)

Bit	Field	Value	Description
8	CIRQ		Card interrupt. This bit is only used for SD and SDIO cards. In 1-bit mode, interrupt source is asynchronous (can be a source of asynchronous wake-up). In 4-bit mode, interrupt source is sampled during the interrupt cycle. In CE-ATA mode, interrupt source is detected when the card drives mmc_cmd line to zero during one cycle after data transmission end. All modes above are fully exclusive. The controller interrupt must be clear by setting SD_IE[8] CIRQ_ENABLE to 0, then the host driver must start the interrupt service with card (clearing card interrupt status) to remove card interrupt source. Otherwise the Controller interrupt will be reasserted as soon as SD_IE[8] CIRQ_ENABLE is set to 1. Writes to this bit are ignored.
		Read 0	No card interrupt
		Read 1	Generate card interrupt
7	CREM		Card Removal. This bit is set automatically when SD_PSTATE[CINS] changes from 1 to 0. A clear of this bit doesn't affect Card inserted present state (SD_PSTATE[CINS]).
		Read 0	Card State stable or debouncing
		Write 0	Status bit unchanged
		Read 1	Card Removed
		Write 1	Status is cleared
6	CINS		Card Insertion. This bit is set automatically when SD_PSTATE[CINS] changes from 0 to 1. A clear of this bit doesn't affect Card inserted present state (SD_PSTATE[CINS]).
		Read 0	Card State stable or debouncing
		Write 0	Status bit unchanged
		Read 1	Card inserted
		Write 1	Status is cleared.
5	BRR		Buffer read ready. This bit is set automatically during a read operation to the card (see class 2 - block oriented read commands) when one block specified by the SD_BLK[10:0] BLEN bit field is completely written in the buffer. It indicates that the memory card has filled out the buffer and that the local host needs to empty the buffer by reading it. NoteIf the DMA receive-mode is enabled, this bit is never set; instead a DMA receive request to the main DMA controller of the system is generated.
		Read 0	Not ready to read buffer
		Write 0	Status bit unchanged
		Read 1	Ready to read buffer
		Write 1	Status is cleared.
4	BWR		Buffer write ready. This bit is set automatically during a write operation to the card (see class 4 - block oriented write command) when the host can write a complete block as specified by SD_BLK[10:0] BLEN. It indicates that the memory card has emptied one block from the buffer and that the local host is able to write one block of data into the buffer. NoteIf the DMA transmit mode is enabled, this bit is never set; instead, a DMA transmit request to the main DMA controller of the system is generated.
		Read 0	Not ready to write buffer
		Write 0	Status bit unchanged
		Read 1	Ready to write buffer
		Write 1	Status is cleared.
3	DMA		DMA Interrupt. This status is set when an interrupt is required in the ADMA instruction and after the data transfer completion.
		Read 0	DMA Interrupt detected
		Write 0	Status bit unchanged
		Read 1	No DMA Interrupt
		Write 1	Status is cleared.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Table 17-38. Interrupt Status Register (SD_STAT) Field Descriptions (continued)

Bit	Field	Value	Description
2	BGE		Block gap event. When a stop at block gap is requested (SD_HCTL[16] SBGR bit), this bit is automatically set when transaction is stopped at the block gap during a read or write operation. This event does not occur when the stop at block gap is requested on the last block. In read mode, a 1-to-0 transition of the mmc_dat line active status (SD_PSTATE[2] DLA bit) between data blocks generates a Block gap event interrupt.
		Read 0	No block gap event
		Write 0	Status bit unchanged
		Read 1	Transaction stopped at block gap
		Write 1	Status is cleared
1	TC		Transfer completed. This bit is always set when a read/write transfer is completed or between two blocks when the transfer is stopped due to a stop at block gap request (SD_HCTL[16] SBGR bit). This bit is also set when exiting a command in a busy state (if the command has a busy notification capability). In Read modeThis bit is automatically set on completion of a read transfer (SD_PSTATE[9] RTA bit). In write modeThis bit is set automatically on completion of the mmc_dat line use (SD_PSTATE[2] DLA bit).
		Read 0	No transfer complete
		Write 0	Status bit unchanged
		Read 1	Data transfer complete
		Write 1	Status is cleared
0	CC		Command complete. This bit is set when a 1-to-0 transition occurs in the register command inhibit (SD_PSTATE[0] CMDI bit) If the command is a type for which no response is expected, then the command complete interrupt is generated at the end of the command. A command timeout error (SD_STAT[16] CTO bit) has higher priority than command complete (SD_STAT[0] CC bit). If a response is expected but none is received, then a command timeout error is detected and signaled instead of the command complete interrupt.
		Read 0	No command complete
		Write 0	Status bit unchanged
		Read 1	Command complete
		Write 1	Status is cleared

17.5.23 Interrupt SD Enable Register (SD_IE)

This register allows to enable/disable the module to set status bits, on an event-by-event basis.

- SD_IE[31:16] = Error Interrupt Status Enable
- SD_IE[15:0] = Normal Interrupt Status Enable

The interrupt SD enable register (SD_IE) is shown in Figure 17-59 and described in Table 17-39.

Figure 17-59. Interrupt SD Enable Register (SD_IE)

17.5.24 Interrupt Signal Enable Register (SD_ISE)

This register allows you to enable/disable the module to set status bits, on an event-by-event basis.

- SD_ISE[31:16] = Error Interrupt Signal Enable
- SD_ISE[15:0] = Normal Interrupt Signal Enable

The Interrupt Signal Enable Register (SD_ISE) is shown in Figure 17-60 and described in Table 17-40.

Figure 17-60. Interrupt Signal Enable Register (SD_ISE)

17.5.25 Auto CMD12 Error Status Register (SD_AC12)

The host driver may determine which of the errors cases related to Auto CMD12 has occurred by checking this SD_AC12 register when an auto CMD12 error interrupt occurs.

This register is valid only when auto CMD12 is enabled (SD_CMD[2] ACEN bit) and auto CMD12Error (SD_STAT[24] ACE bit) is set to 1.

NOTE: These bits are automatically reset when starting a new adtc command with data.

The auto CMD12 error status register (SD_AC12) is shown in Figure 17-61 and described in Table 17-41.

Figure 17-61. Auto CMD12 Error Status Register (SD_AC12)

31	8	7	6	5	4	3	2	1	0
Reserved		CNI	Reserved		ACIE	ACEB	ACCE	ACTO	ACNE
R-0		R-0	R-0		R-0	R-0	R-0	R-0	R-0

LEGENDR/W = Read/Write; R = Read only; -*n* = value after reset

Table 17-41. Auto CMD12 Error Status Register (SD_AC12) Field Descriptions

Bit	Field	Value	Description
31-8	Reserved	0	Reserved bit field. Do not write any value.
7	CNI		Command not issue by auto CMD12 error. If this bit is set to 1, it means that pending command is not executed due to auto CMD12 error ACEB, ACCE, ACTO, or ACNE.
		Read 0	Not error
		Read 1	Command not issued
6-5	Reserved	0	Reserved bit field. Do not write any value.
4	ACIE		Auto CMD12 index error. This bit is a set to 1 when response index differs from corresponding command auto CMD12 index previously emitted.
			This bit depends on the command index check enable (SD_CMD[20] CICE bit).
		Read 0	No error
		Read 1	Auto CMD12 index error
3	ACEB		Auto CMD12 end bit error. This bit is set to 1 when detecting a 0 at the end bit position of auto CMD12 command response.
		Read 0	No error
		Read 1	AutoCMD12 end bit error
2	ACCE		Auto CMD12 CRC error. This bit is automatically set to 1 when a CRC7 error is detected in the auto CMD12 command response depending on the enable in the SD_CMD[19] CCCE bit.
		Read 0	No error
		Read 1	Auto CMD12 CRC error
1	ACTO		Auto CMD12 timeout error. This bit is set to 1 if no response is received within 64 clock cycles from the end bit of the auto CMD12 command.
		Read 0	No error
		Read 1	Auto CMD12 time out
0	ACNE		Auto CMD12 not executed. This bit is set to 1 if multiple block data transfer command has started and if an error occurs in command before auto CMD12 starts.
		Read 0	Auto CMD12 executed
		Read 1	Auto CMD12 not executed

Table 17-42. Capabilities Register (SD_CAPA) Field Descriptions (continued)

Bit	Field	Value	Description
23	SRS		Suspend/resume support (SDIO cards only). This bit indicates whether the host controller supports Suspend/Resume functionality.
		Read 0	The Host controller does not suspend/resume functionality.
		Read 1	The Host controller supports suspend/resume functionality.
22	DS		DMA support. This bit indicates that the Host controller is able to use DMA to transfer data between system memory and the Host controller directly.
		Read 0	DMA not supported
		Read 1	DMA supported
21	HSS		High-speed support. This bit indicates that the host controller supports high speed operations and can supply an up-to-52 MHz clock to the card.
		Read 0	DMA not supported
		Read 1	DMA supported
20	Reserved	0	Reserved bit field. Do not write any value.
19	AD2S		This bit indicates whether the Host Controller is capable of using ADMA2. It depends on setting of generic parameter MADMA_EN.
		Read 0	ADMA2 supported
		Read 1	ADMA2 not supported
18	Reserved	0	Reserved bit field. Do not write any value.
17-16	MBL		Maximum block length. This value indicates the maximum block size that the host driver can read and write to the buffer in the host controller.
			The host controller supports 512 bytes and 1024 bytes block transfers.
		Read 0	512 bytes
		Read 1	1024 bytes
		Read 2	2048 bytes
15-14	Reserved	0	Reserved bit field. Do not write any value.
13-8	BCF		Base clock frequency for clock provided to the card.
		Read 0	The value indicating the base (maximum) frequency for the output clock provided to the card is system dependent and is not available in this register. Get the information via another method. See the *Power, Reset, and Clock Management* chapter for more information on the value of FUNC_96M_CLK clock signal.
7	TCU		Timeout clock unit. This bit shows the unit of base clock frequency used to detect Data Timeout Error (SD_STAT[20] DTO bit).
		Read 0	kHz
		Read 1	MHz
6	Reserved	0	Reserved. This bit is initialized to zero, and writes to it are ignored.
5-0	TCF		Timeout clock frequency. The timeout clock frequency is used to detect Data Timeout Error (SD_STAT[20] DTO bit).
		Read 0	The timeout clock frequency depends on the frequency of the clock provided to the card. The value of the timeout clock frequency is not available in this register.

17.5.27 Maximum Current Capabilities Register (SD_CUR_CAPA)

This register indicates the maximum current capability for each voltage. The value is meaningful if the voltage support is set in the capabilities register (SD_CAPA).

Initialization of this register (via a write access to this register) depends on the system capabilities. The host driver shall not modify this register after the initialization.

This register is only reinitialized by a hard reset (via mmc_RESET signal). The maximum current capabilities register (SD_CUR_CAPA) is shown in Figure 17-63 and described in Table 17-43.

Figure 17-63. Maximum Current Capabilities Register (SD_CUR_CAPA)

17.5.28 Force Event Register for Error Interrupt Status (SD_FE)

The Force Event register is not a physically implemented register. Rather, it is an address at which the Error Interrupt Status register can be written. The effect of a write to this address will be reflected in the Error Interrupt Status Register, if corresponding bit of the Error Interrupt Status Enable Register is set.

The force event register (SD_FE) is shown in Figure 17-64 and described in Table 17-44.

17.5.29 ADMA Error Status Register (SD_ADMAES)

When an ADMA Error Interrupt has occurred, the ADMA Error States field in this register holds the ADMA state and the ADMA System Address Register holds the address around the error descriptor. For recovering the error, the Host Driver requires the ADMA state to identify the error descriptor address as follows:

- ST_STOP: Previous location set in the ADMA System Address register is the error descriptor address.
- ST_FDS: Current location set in the ADMA System Address register is the error descriptor address.
- ST_CADR: This sate is never set because do not generate ADMA error in this state.
- ST_TFR: Previous location set in the ADMA System Address register is the error descriptor address.

In the case of a write operation, the Host Driver should use ACMD22 to get the number of written block rather than using this information, since unwritten data may exist in the Host Controller. The Host Controller generates the ADMA Error Interrupt when it detects invalid descriptor data (Valid = 0) at the ST_FDS state. In this case, ADMA Error State indicates that an error occurs at ST_FDS state. The Host Driver may find that the Valid bit is not set in the error descriptor.

The ADMA error status register (SD_BLK) is shown in Figure 17-65 and described in Table 17-45.

Figure 17-65. ADMA Error Status Register (SD_ADMAES)

31	3	2	1	0
Reserved		LME	AES	
R-0		W-0	R/W-0	

LEGENDR/W = Read/Write; R = Read only; -*n* = value after reset

Table 17-45. ADMA Error Status Register (SD_ADMAES) Field Descriptions

Bit	Field	Value	Description
31-3	Reserved	0	Reserved bit field. Do not write any value.
2	LME		ADMA Length Mismatch Error: • While Block Count Enable is being set, the total data length specified by the Descriptor table is different from that specified by the Block Count and Block Length. • Total data length cannot be divided by the block length.
		0	No error
		1	Error
1-0	AES		ADMA Error State. This field indicates the state of ADMA when an error occurred during an ADMA data transfer. This field never indicates "10" because ADMA never stops in this state.
		Read 0	ST_STOP (Stop DMA). Contents of the SYS_SDR register
		Write 1h	ST_STOP (Stop DMA). Points to the error descriptor.
		Read 2h	Never set this state. (Not used)
		Write 3h	ST_TFR (Transfer Data). Points to the 'next' of the error descriptor.

17.5.30 ADMA System Address Low Bits Register (SD_ADMASAL)

This register holds the byte address of the executing command of the Descriptor table. The 32-bit Address Descriptor uses the lower 32 bits of this register. At the start of ADMA, the Host Driver shall set the start address of the Descriptor table.

The ADMA System address low bits register (SD_ADMASAL) is shown in Figure 17-66 and described in Table 17-46.

Figure 17-66. ADMA System Address Low Bits (SD_ADMASAL)

31	0
ADMA_A32B	
R/W-0	

LEGENDR/W = Read/Write; R = Read only; -*n* = value after reset

Table 17-46. ADMA System Address Low Bits (SD_ADMASAL) Field Descriptions

Bit	Field	Value	Description
31-0	ADMA_A32B		The ADMA increments this register address, which points to the next line, whenever fetching a Descriptor line. When the ADMA Error Interrupt is generated, this register holds the valid Descriptor address depending on the ADMA state. The Host Driver shall program the Descriptor Table on a 32-bit boundary and set the 32-bit boundary address to this register. ADMA2 ignores the lower 2 bits of this register and assumes it to be 00b.

17.5.31 ADMA System Address High Bits Register (SD_ADMASAH)

The ADMA System address high bits register (SD_ADMASAH) is shown in Figure 17-66 and described in Table 17-46.

17.5.32 Versions Register (SD_REV)

This register contains the hard coded RTL vendor revision number, the version number of SD specification compliancy and a slot status bit.

- SD_REV[31:16] = Host Controller Version
- SD_REV[15:0] = Slot Interrupt Status

The versions register (SD_REV) is shown in Figure 17-68 and described in Table 17-48.

Figure 17-68. Versions Register (SD_REV)

31–24	23–16	15–1	0
VREV	SREV	Reserved	SIS
R-x	R-0	R-0	R-0

LEGENDR/W = Read/Write; R = Read only; *-n* = value after reset

Table 17-48. Versions Register (SD_REV) Field Descriptions

Bit	Field	Value	Description
31-24	VREV	0	Vendor Version Number. Bits [7:4] is the major revision, bits [3:0] is the minor revision. Examples: 10h for 1.0 21h for 2.1
23-16	SREV	Read 0	Specification Version Number. This status indicates the Standard SD Host Controller Specification Version. The upper and lower 4-bits indicate the version. SD Host Specification Version 1.0
15-1	Reserved	0	Reserved bit field. Do not write any value.
0	SIS		Slot Interrupt Status. This status bit indicates the inverted state of interrupt signal for the module. By a power on reset or by setting a software reset for all (SD_SYSCTL[24] SRA), the interrupt signal shall be deasserted and this status shall read 0.

18.1 Introduction

18.1.1 UART Mode Features

The general features of the UART/IrDA module when operating in UART mode are:

- 16C750 compatibility
- Baud rate from 300 bps up to 3.6864 Mbps
- Auto-baud between 1200 bps and 115.2 Kbps
- Software/Hardware flow control
  - Programmable Xon/Xoff characters
  - Programmable Auto-RTS and Auto CTS
- Programmable serial interface characteristics
  - 5, 6, 7, or 8-bit characters
  - Even, odd, mark (always 1), space (always 0), or no parity (non-parity bit frame) bit generation and detection
  - 1, 1.5, or 2 stop bit generation
- False start bit detection
- Line break generation and detection
- Modem control functions (CTS, RTS, DSR, DTR, RI, and DCD)
- Fully prioritized interrupt system controls
- Internal test and loopback capabilities

18.1.2 IrDA Mode Features

The general features of the UART/IrDA when operating in IrDA or CIR mode are:

- Support of IrDA 1.4 slow infrared (SIR), medium infrared (MIR) and fast infrared (FIR) communications (very fast infrared (VFIR) is not supported).
- Frame formatting: addition of variable xBOF characters and EOF characters
- Uplink/downlink CRC generation/detection
- Asynchronous transparency (automatic insertion of break character)
- 8-entry status FIFO (with selectable trigger levels) available to monitor frame length and frame errors
- Framing error, cyclic redundancy check (CRC) error, illegal symbol (FIR), abort pattern (SIR, MIR) detection
- Support of consumer infrared (CIR) for remote control applications.
- Transmit and receive
- Free data format (supports any remote control private standards)
- Selectable bit rate
- Configurable carrier frequency
- 1/2, 5/12, 1/3 or 1/4 carrier duty cycle

18.1.3 Unsupported UART Features

The following UART/IrDA module features are not supported in this device.

Table 18-1. Unsupported UART Features

Feature	Reason
Full modem control on UART0	DCD, DSR, DTR, RI not pinned-out
Full modem control on UART2-5	DCD, DSR, DTR, RI not pinned-out
Device wake-up on UART1-5	Wake-up not supported - no SWake connection

18.2 Intregration

This device contains 6 instantiations of the UART/IrDA (UARTIRDAOCP) peripheral. There are six UART modules called UART0 – UART5. UART0 provides wakeup capability. Only UART 1 provides full modem control signals. All UARTs support IrDA and CIR modes and RTS/CTS flow control (subject to pin muxing configuration). Figure 18-1 shows an example of system connectivity using UART communication with hardware handshake.

Figure 18-1. UART/IrDA Module — UART Application

Figure 18-2 shows an example of system connectivity using infrared communication with remote control (consumer infrared).

Figure 18-2. UART/IrDA Module — IrDA/CIR Application

18.2.1 UART Connectivity Attributes

The general connectivity attributes for each of the UART modules are shown in Table 18-2 and Table 18-3.

Table 18-2. UART0 Connectivity Attributes

Attributes	Type
Power Domain	Wake-Up Domain
Clock Domain	PD_WKUP_L4_WKUP_GCLK (OCP) PD_WKUP_UART0_GFCLK (Func)
Reset Signals	WKUP_DOM_RST_N
Idle/Wakeup Signals	Smart Idle / Wakeup
Interrupt Requests	1 interrupt to MPU Subsystem, PRUSS and WakeM3
DMA Requests	2 DMA requests to EDMA
Physical Address	L4 Wakeup slave port

Table 18-3. UART1–5 Connectivity Attributes

Attributes	Type
Power Domain	Peripheral Domain
Clock Domain	PD_PER_L4LS_GCLK (OCP) PD_PER_UART_GFCLK (Func)
Reset Signals	PER_DOM_RST_N
Idle/Wakeup Signals	Smart Idle
Interrupt Requests	UART1-2 1 interrupt to MPU Subsystem and PRUSS UART3-5 1 interrupt to MPU Subsystem only
DMA Requests	2 DMA requests to EDMA
Physical Address	L4 Peripheral slave port

18.2.2 UART Clock and Reset Management

The UART modules use separate functional and bus interface clocks.

Table 18-4. UART0 Clock Signals

Clock Signal	Max Freq	Reference / Source	Comments
CLK			
Interface clock	100 MHz	CORE_CLKOUTM4 / 2	pd_wkup_l4_wkup_gclk

Copyright © 2011, Texas Instruments Incorporated

DRAFT ONLY

Table 18-4. UART0 Clock Signals (continued)

Clock Signal	Max Freq	Reference / Source	Comments
From PRCM			
FCLK			
Functional clock	48 MHz	PER_CLKOUTM2 / 4	pd_wkup_uart0_gfclk
from PRCM			

Table 18-5. UART1–5 Clock Signals

Clock Signal	Max Freq	Reference / Source	Comments
CLK Interface clock	100 MHz	CORE_CLKOUTM4 / 2	pd_per_l4ls_gclk From PRCM
FCLK Functional clock	48 MHz	PER_CLKOUTM2 / 4	pd_per_uart_gfclk From PRCM

For UART operation, the functional clock is used to produce a baud rate up to 3.6M bits/s. Table 18-6 lists the supported baud rates, the requested divider, and the corresponding error versus the standard baud rate.

Table 18-6. UART Mode Baud and Error Rates

Baud rate	Over sampling	Divisor	Error (%)
300	16	10000	0
600	16	5000	0
1200	16	2500	0
2400	16	1250	0
4800	16	625	0
9600	16	313	0.16
14400	16	208	0.16
19200	16	156	0.16
28800	16	104	0.16
38400	16	78	0.16
57600	16	52	0.16
115200	16	26	0.16
230400	16	13	0.16
460800	13	8	0.16
921600	13	4	0.16
1843200	13	2	0.16
3000000	16	1	0
3686400	13	1	0.16

For IrDA operation, the internal functional clock divisor allows generation of SIR, MIR, or FIR baud rates as shown in Table 18-7.

Table 18-7. IrDA Mode Baud and Error Rates

Baud rate	IR mode	Encoding	Divisor	Error (%)
2400	SIR	3/16	1250	0
9600	SIR	3/16	312	0.16
19200	SIR	3/16	156	0.16
38400	SIR	3/16	78	0.16
57600	SIR	3/16	52	0.16
115200	SIR	3/16	26	0.16

Table 18-7. IrDA Mode Baud and Error Rates (continued)

Baud rate	IR mode	Encoding	Divisor	Error (%)
576000	MIR	1/4	2	0
1152000	MIR	1/4	1	0
4000000	FIR	4PPM	1	0

18.2.3 UART Pin List

The UART interface pins are listed in Table 18-8. Pin functionality depends on the selected operating mode of the module.

Table 18-8. UART Pin List

Pin	Type	Description
UARTx_RXD	I	UART / IrDA / CIR Receive Data
UARTx_TXD / IRTX / RCTX	OZ	UART / IrDA / CIR Transmit Data
UARTx_RTSn / SD	OZ	UART Request to Send / IrDA Mode
UARTx_CTSn	I	UART Clear to Send
UARTx_DTRn[(1)]	OZ	UART Data Terminal Ready
UARTx_DSRn[(1)]	I	UART Data Set Ready
UARTx_DCDn[(1)]	I	UART Data Carrier Detect
UARTx_RIN[(1)]	1	UART Ring Indicator

(1) UART1 only

The UART module includes mode selection outputs to control the function of multiplexed signal based on the selected operating mode. The IRDA_SELECT signal indicates IrDA mode and the RC signal indicates CIR mode. The signal muxing based on these control outputs is shown in Table 18-9.

Table 18-9. UART Muxing Control

RC	IRDA_SELECT	UARTx_TXD / IRTX / RCTX Function	UARTx_RTSn / SD Function	UARTx_CTSn Function	Mode
0	0	TXD	RTSn	CTSn	UART
0	1	IRTX	SD	not used	IrDA
1	0	RCTX	SD	not used	CIR
1	1	n/a	n/a	n/a	Not Valid

18.3 Functional Description

18.3.1 Block Diagram

The UART/IrDA/CIR module can be divided into three main blocks:

- FIFO management
- Mode selection
- Protocol formatting

FIFO management is common to all functions and enables the transmission and reception of data from the host processor point of view.

There are two modes:

- Function mode: Routes the data to the chosen function (UART, IrDA, or CIR) and enables the mechanism corresponding to the chosen function
- Register mode: Enables conditional access to registers

For more information about mode configuration, see Section 18.3.7, *Mode Selection*.

Protocol formatting has three subcategories:

- Clock generation: The 48-MHz input clock generates all necessary clocks.
- Data formatting: Each function uses its own state-machine that is responsible for the transition between FIFO data and frame data associated with it.
- Interrupt management: Different interrupt types are generated depending on the chosen function:
  - UART mode interrupts: Seven interrupts prioritized in six different levels
  - IrDA mode interrupts: Eight interrupts. The interrupt line is activated when any interrupt is generated (there is no priority).
  - CIR mode interrupts: A subset of existing IrDA mode interrupts is used.

  In each mode, when an interrupt is generated, the UART_IIR register indicates the interrupt type.

In parallel with these functional blocks, a power-saving strategy exists for each function.

Figure 18-3 is the UART/IrDA/CIR block diagram.

Figure 18-3. UART/IrDA/CIR Functional Specification Block Diagram

18.3.2 Clock Configuration

Each UART uses a 48-MHz functional clock for its logic and to generate external interface signals. Each UART uses an interface clock for register accesses. The PRCM module generates and controls all these clocks (for more information, see , *Clock Domain Module Attributes*, in Chapter 7, *Power, Reset, and Clock Management*).

The idle and wake-up processes use a handshake protocol between the PRCM and the UART (for a description of the protocol, see , *Module-Level Clock Managment*, in Chapter 7, *Power, Reset, and Clock Management*). The UARTi.UART_SYSC[4:3] IDLEMODE bit field controls UART idle mode.

18.3.3 Software Reset

The UARTi.UART_SYSC[1] SOFTRESET bit controls the software reset; setting this bit to 1 triggers a software reset functionally equivalent to hardware reset.

18.3.4 Power Management

18.3.4.1 UART Mode Power Management

18.3.4.1.1 Module Power Saving

In UART modes, sleep mode is enabled by setting the UARTi.UART_IER[4] SLEEP_MODE bit to 1 (when the UARTi.UART_EFR[4] ENHANCED_EN bit is set to 1).

Sleep mode is entered when all the following conditions exist:

- The serial data input line, uarti_rx, is idle.
- The TX FIFO and TX shift register are empty.
- The RX FIFO is empty.
- The only pending interrupts are THR interrupts.

Copyright © 2011, Texas Instruments Incorporated

Sleep mode is a good way to lower UART power consumption, but this state can be achieved only when the UART is set to modem mode. Therefore, even if the UART has no key role functionally, it must be initialized in a functional mode to take advantage of sleep mode.

In sleep mode, the module clock and baud rate clock are stopped internally. Because most registers are clocked by these clocks, this greatly reduces power consumption. The module wakes up when a change is detected on the uarti_rx line, when data is written to the TX FIFO, and when there is a change in the state of the modem input pins.

An interrupt can be generated on a wake-up event by setting the UARTi.UART_SCR[4] RX_CTS_WU_EN bit to 1. To understand how to manage the interrupt, see Section 18.3.5.1.2, *Wake-Up Interrupt*.

NOTE: There must be no writing to the divisor latches, UARTi.UART_DLL and UARTi.UART_DLH, to set the baud clock (BCLK) while in sleep mode. It is advisable to disable sleep mode using the UARTi.UART_IER[4] SLEEP_MODE bit before writing to the UARTi.UART_DLL register or the UARTi.UART_DLH register.

18.3.4.1.2 System Power Saving

Sleep and auto-idle modes are embedded power-saving features. Power-reduction techniques can be applied at the system level by shutting down certain internal clock and power domains of the device.

The UART supports an idle req/idle ack handshaking protocol used at the system level to shut down the UART clocks in a clean and controlled manner and to switch the UART from interrupt-generation mode to wake-up generation mode for unmasked events (see the UARTi.UART_SYSC[2] ENAWAKEUP bit and the UARTi.UART_WER register).

For more information, see , *Module Level Clock Managment*, in Chapter 7, *Power, Reset, and Clock Management*.

18.3.4.2 IrDA Mode Power Management (UART3 Only)

18.3.4.2.1 Module Power Saving

In IrDA modes, sleep mode is enabled by setting the UART3.MDR[3] IR_SLEEP bit to 1.

Sleep mode is entered when all the following conditions exist:

- The serial data input line, uart3.rx_irrx, is idle.
- The TX FIFO and TX shift register are empty.
- The RX FIFO is empty.
- No interrupts are pending except THR interrupts.

The module wakes up when a change is detected on the uart3_rx_irrx line or when data is written to the TX FIFO.

18.3.4.2.2 System Power Saving

System power saving for the IrDA mode has the same function as for the UART mode (see Section 18.3.4.1.2, *System Power Saving*).

18.3.4.3 CIR Mode Power Management (UART3 Only)

18.3.4.3.1 Module Power Saving

Module power saving for the CIR mode has the same function as for the IrDA mode (see Section 18.3.4.2.1, *Module Power Saving*).

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

18.3.4.3.2 System Power Saving

System power saving for the CIR mode has the same function as for the UART mode (see Section 18.3.4.1.2, *System Power Saving*).

18.3.4.4 Local Power Management

Table 18-10 describes power-management features available for the UART.

NOTE: For information about source clock gating and sleep/wake-up transitions description, see , *Module-Level Clock Managment*, in Chapter 7, *Power, Reset, and Clock Management*.

Table 18-10. Local Power-Management Features

Feature	Registers	Description
Clock autogating	UART_SYSC[0] AUTOIDLE	This bit allows local power optimization in the module by gating the UARTi_ICLK clock on interface activity or gating the UARTi_FCLK clock on internal activity.
Slave idle modes	UART_SYSC[4:3] IDLEMODE	Force-idle, no-idle, smart-idle, and smart-idle wakeup-capable modes are available
Clock activity	N/A	Feature not available
Master standby modes	N/A	Feature not available
Global wake-up enable	UART_SYSC[2] ENAWAKEUP	This bit enables the wake-up feature at module level.
Wake-Up sources enable	N/A	Feature not available

18.3.5 Interrupt Requests

18.3.5.1 UART Mode Interrupt Management

18.3.5.1.1 UART Interrupts

UART mode includes seven possible interrupts prioritized to six levels.

When an interrupt is generated, the interrupt identification register (UARTi.UART_IIR) sets the UARTi.UART_IIR[0] IT_PENDING bit to 0 to indicate that an interrupt is pending, and indicates the type of interrupt through the UARTi.UART_IIR[5:1] bit field. Table 18-11 summarizes the interrupt control functions.

Table 18-11. UART Mode Interrupts

UART_IIR[5:0]	Priority Level	Interrupt Type	Interrupt Source	Interrupt Reset Method
000001	None	None	None	None
000110	1	Receiver line status	OE, FE, PE, or BI errors occur in characters in the RX FIFO.	FE, PE, BI: Read the UART_RHR register. OE: Read the UART_LSR register.
001100	2	RX time-out	Stale data in RX FIFO	Read the UART_RHR register.
000100	2	RHR interrupt	DRDY (data ready) (FIFO disable) RX FIFO above trigger level (FIFO enable)	Read the UART_RHR register until the interrupt condition disappears.
000010	3	THR interrupt	TFE (UART_THR empty) (FIFO disable) TX FIFO below trigger level (FIFO enable)	Write to the UART_THR until the interrupt condition disappears.
000000	4	Modem status	See the UART_MSR register.	Read the UART_MSR register.

Copyright © 2011, Texas Instruments Incorporated

DRAFT ONLY

Table 18-11. UART Mode Interrupts (continued)

UART_IIR[5:0]	Priority Level	Interrupt Type	Interrupt Source	Interrupt Reset Method
010000	5	XOFF interrupt/special character interrupt	Receive XOFF characters/special character	Receive XON character(s), if XOFF interrupt/read of the UART_IIR register, if special character interrupt.
100000	6	CTS, RTS	RTS pin or CTS pin change state from active (low) to inactive (high).	Read the UART_IIR register.

For the receiver-line status interrupt, the RX_FIFO_STS bit (UARTi.UART_LSR[7]) generates the interrupt.

For the XOFF interrupt, if an XOFF flow character detection caused the interrupt, the interrupt is cleared by an XON flow character detection. If special character detection caused the interrupt, the interrupt is cleared by a read of the UARTi.UART_IIR register.

18.3.5.1.2 Wake-Up Interrupt

Wake-up interrupt is a special interrupt that works differently from other interrupts. This interrupt is enabled when the UARTi.UART_SCR[4] RX_CTS_WU_EN bit is set to 1. The UARTi.UART_IIR register is not modified when this occurs; the UART3.UART_SSR[1] RX_CTS_WU_STS bit must be checked to detect a wake-up event.

When a wake-up interrupt occurs, it can be cleared only by resetting the UARTi.UART_SCR[4] RX_CTS_WU_EN bit. This bit must be reenabled (set to 1) after the current wake-up interrupt event is processed to detect the next incoming wake-up event.

18.3.5.2 IrDA Mode Interrupt Management

18.3.5.2.1 IrDA Interrupts

The IrDA function generates interrupts. All interrupts can be enabled and disabled by writing to the appropriate bit in the interrupt enable register (UART3.UART_IER). The interrupt status of the device can be checked by reading the interrupt identification register (UART3.UART_IIR).

UART, IrDA, and CIR modes have different interrupts in the UART/IrDA/CIR module and, therefore, different UART3.UART_IER and UART3.UART_IIR mappings, depending on the selected mode.

IrDA modes have eight possible interrupts (see Table 18-12). The interrupt line is activated when any interrupt is generated (there is no priority).

Table 18-12. IrDA Mode Interrupts

UART_IIR Bit	Interrupt Type	Interrupt Source	Interrupt Reset Method
0	RHR interrupt	DRDY (data ready) (FIFO disable) RX FIFO above trigger level (FIFO enable)	Read the UART_RHR register until the interrupt condition disappears.
1	THR interrupt	TFE (UART_THR empty) (FIFO disable) TX FIFO below trigger level (FIFO enable)	Write to the UART_THR until the interrupt condition disappears.
2	Last byte in RX FIFO	Last byte of frame in RX FIFO is available to be read at the RHR port.	Read the UART_RHR register.
3	RX overrun	Write to the UART_RHR register when the RX FIFO is full.	Read UART_RESUME register.
4	Status FIFO interrupt	Status FIFO triggers level reached.	Read STATUS FIFO.

Copyright © 2011, Texas Instruments Incorporated

Table 18-12. IrDA Mode Interrupts (continued)

UART_IIR Bit	Interrupt Type	Interrupt Source	Interrupt Reset Method
5	TX status	1. UART_THR empty before EOF sent. Last bit of transmission of the IrDA frame occurred, but with an underrun error. OR 2. Transmission of the last bit of the IrDA frame completed successfully.	1. Read the UART_RESUME register. OR 2. Read the UART_IIR register.
6	Receiver line status interrupt	CRC, ABORT, or frame-length error is written into the STATUS FIFO.	Read the STATUS FIFO (read until empty - maximum of eight reads required).
7	Received EOF	Received end-of-frame	Read the UART_IIR register.

18.3.5.2.2 Wake-Up Interrupts

The wake-up interrupt for IrDA mode has the same function as that for UART mode (see Section 18.3.5.1.2, *Wake-Up Interrupt*).

CAUTION

Wake-Up interface implementation in this mode is based on the UARTi_SIDLEACK low-to-high transition instead of the UARTi_SIDLEACK state.

This does not ensure wake-up event generation as expected when configured in smart-idle mode, and the system wakes up for a short period.

18.3.5.3 CIR Mode Interrupt Management

18.3.5.3.1 CIR Interrupts

The CIR function generates interrupts that can be enabled and disabled by writing to the appropriate bit in the interrupt enable register (UART3.UART_IER). The interrupt status of the device can be checked by reading the interrupt identification register (UART3.UART_IIR).

UART, IrDA, and CIR modes have different interrupts in the UART/IrDA/CIR module and, therefore, different UART3.UART_IER and UART3.UART_IIR mappings, depending on the selected mode.

Table 18-13 lists the interrupt modes to be maintained. In CIR mode, the sole purpose of the UART3.UART_IIR[5] bit is to indicate that the last bit of infrared data was passed to the uart3_cts_rctx pin.

Table 18-13. CIR Mode Interrupts

UART_IIR Bit Number	Interrupt Type	Interrupt Source	Interrupt Reset Method
0	N/A for CIR mode	N/A for CIR mode	N/A for CIR mode
1	THR interrupt	TFE (UART_THR empty) (FIFO disable) TX FIFO below trigger level (FIFO enable)	Write to the UART_THR register until the interrupt condition disappears.
2	N/A for CIR mode	N/A for CIR mode	N/A for CIR mode
3	N/A for CIR mode	N/A for CIR mode	N/A for CIR mode
4	N/A for CIR mode	N/A for CIR mode	N/A for CIR mode
5	TX status	Transmission of the last bit of the frame is complete successfully.	Read the UART_IIR register.

Copyright © 2011, Texas Instruments Incorporated

Table 18-13. CIR Mode Interrupts (continued)

UART_IIR Bit Number	Interrupt Type	Interrupt Source	Interrupt Reset Method
6	N/A for CIR mode	N/A for CIR mode	N/A for CIR mode
7	N/A for CIR mode	N/A for CIR mode	N/A for CIR mode

18.3.5.3.2 Wake-Up Interrupts

The wake-up interrupt for CIR mode has the same function as that for UART mode (see Section 18.3.5.1.2, *Wake-Up Interrupt*).

18.3.6 FIFO Management

The FIFO is accessed by reading and writing the UARTi.UART_RHR and UARTi.UART_THR registers. Parameters are controlled using the FIFO control register (UARTi.UART_FCR) and supplementary control register (UARTi.UART_SCR). Reading the UARTi.UART_SSR[0] TX_FIFO_FULL bit at 1 means the FIFO is full.

The UARTi.UART_TLR register controls the FIFO trigger level, which enables DMA and interrupt generation. After reset, transmit (TX) and receive (RX) FIFOs are disabled; thus, the trigger level is the default value of 1 byte. Figure 18-4 shows the FIFO management registers.

NOTE: Data in the UARTi.UART_RHR register is not overwritten when an overflow occurs.

NOTE: The UARTi.UART_SFLSR, UARTi.UART_SFREGL, and UARTi.UART_SFREGH status registers are used in IrDA mode only. For use, see Section 18.3.8.2.3, *IrDA Data Formatting*.

18.3.6.1 FIFO Trigger

18.3.6.1.1 Transmit FIFO Trigger

Table 18-14 lists the TX FIFO trigger level settings.

Table 18-14. TX FIFO Trigger Level Setting Summary

UART_SCR[6]	UART_TLR[3:0]	TX FIFO Trigger Level
0	= 0x0	Defined by the UARTi.UART_FCR[5:4] TX_FIFO_TRIG bit field (8,16, 32, or 56 spaces)
0	!= 0x0	Defined by the UARTi.UART_TLR[3:0] TX_FIFO_TRIG_DMA bit field (from 4 to 60 spaces with a granularity of 4 spaces)
1	Value	Defined by the concatenated value of TX_FIFO_TRIG_DMA and TX_FIFO_TRIG (from 1 to 63 spaces with a granularity of 1 space) **Note:** The combination of TX_FIFO_TRIG_DMA = 0x0 and TX_FIFO_TRIG = 0x0 (all zeros) is not supported (minimum of one space required). All zeros result in unpredictable behavior.

18.3.6.1.2 Receive FIFO Trigger

Table 18-15 lists the RX FIFO trigger level settings.

Table 18-15. RX FIFO Trigger Level Setting Summary

UART_SCR[7]	UART_TLR[7:4]	RX FIFO Trigger Level
0	= 0x0	Defined by the UARTi.UART_FCR[7:6] RX_FIFO_TRIG bit field (8,16, 56, or 60 characters)
0	!= 0x0	Defined by the UARTi.UART_TLR[7:4] RX_FIFO_TRIG_DMA bit field (from 4 to 60 characters with a granularity of 4 characters)
1	Value	Defined by the concatenated value of RX_FIFO_TRIG_DMA and RX_FIFO_TRIG (from 1 to 63 characters with a granularity of 1 character) **Note:** The combination of RX_FIFO_TRIG_DMA = 0x0 and RX_FIFO_TRIG = 0x0 (all zeros) is not supported (minimum of one character required). All zeros result in unpredictable behavior.

The receive threshold is programmed using the UARTi.UART_TCR[7:4] RX_FIFO_TRIG_START and UARTi.UART_TCR[3:0] RX_FIFO_TRIG_HALT bit fields:

- Trigger levels from 0 to 60 bytes are available with a granularity of 4 (trigger level = 4 x [4-bit register value]).
- To ensure correct device operation, ensure that RX_FIFO_TRIG_HALT RX_FIFO_TRIG when auto-RTS is enabled.

  Delay = [4 + 16 x (1 + CHAR_LENGTH + Parity + Stop 0.5)] x Baud_rate + 4 x FCLK

  NOTE: The RTS signal is deasserted after the UART module receives the data over RX_FIFO_TRIG_HALT. Delay means how long the UART module takes to deassert the RTS signal after reaching RX_FIFO_TRIG_HALT.

- In FIFO interrupt mode with flow control, ensure that the trigger level to HALT transmission is greater than or equal to the RX FIFO trigger level (the UARTi.UART_TCR[7:4] RX_FIFO_TRIG_START bit field or the UARTi.UART_FCR[7:6] RX_FIFO_TRIG bit field); otherwise, FIFO operation stalls. In FIFO DMA mode with flow control, this concept does not exist, because a DMA request is sent when a byte is received.

18.3.6.2 FIFO Interrupt Mode

In FIFO interrupt mode (the FIFO control register UARTi.UART_FCR[0] FIFO_EN bit is set to 1 and

DRAFT ONLY

relevant interrupts are enabled by the UARTi.UART_IER register), an interrupt signal informs the processor of the status of the receiver and transmitter. These interrupts are raised when the RX/TX FIFO threshold (the UARTi.UART_TLR[7:4] RX_FIFO_TRIG_DMA and UARTi.UART_TLR[3:0] TX_FIFO_TRIG_DMA bit fields or the UARTi.UART_FCR[7:6] RX_FIFO_TRIG and UARTi.UART_FCR[5:4] TX_FIFO_TRIG bit fields, respectively) is reached.

The interrupt signals instruct the MPU to transfer data to the destination (from the UART in receive mode and/or from any source to the UART FIFO in transmit mode).

When UART flow control is enabled with interrupt capabilities, the UART flow control FIFO threshold (the UARTi.UART_TCR[3:0] RX_FIFO_TRIG_HALT bit field) must be greater than or equal to the RX FIFO threshold.

Figure 18-5 shows the generation of the RX FIFO interrupt request.

Figure 18-5. RX FIFO Interrupt Request Generation

In receive mode, no interrupt is generated until the RX FIFO reaches its threshold. Once low, the interrupt can be deasserted only when the MPU has handled enough bytes to put the FIFO level below threshold. The flow control threshold is set at a higher value than the FIFO threshold.

Figure 18-6 shows the generation of the TX FIFO interrupt request.

Figure 18-6. TX FIFO Interrupt Request Generation

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

In transmit mode, an interrupt request is automatically asserted when the TX FIFO is empty. This request is deasserted when the TX FIFO crosses the threshold level. The interrupt line is deasserted until a sufficient number of elements is transmitted to go below the TX FIFO threshold.

18.3.6.3 FIFO Polled Mode Operation

In FIFO polled mode (the UARTi.UART_FCR[0] FIFO_EN bit is set to 0 and the relevant interrupts are disabled by the UARTi.UART_IER register), the status of the receiver and transmitter can be checked by polling the line status register (UARTi.UART_LSR).

This mode is an alternative to the FIFO interrupt mode of operation in which the status of the receiver and transmitter is automatically determined by sending interrupts to the MPU.

18.3.6.4 FIFO DMA Mode Operation

Although DMA operation includes four modes (DMA modes 0 through 3), the information in assumes that mode 1 is used. (Mode 2 and mode 3 are legacy modes that use only one DMA request for each module.)

In mode 2, the remaining DMA request is used for RX. In mode 3, the remaining DMA request is used for TX.

DMA requests in mode 2 and mode 3 use the following signals:

- S_DMA_48
- S_DMA_50
- S_DMA_52/D_DMA_10
- S_DMA_54

The following signals are not used by the module in mode 2 and mode 3:

- S_DMA_49
- S_DMA_51
- S_DMA_53/D_DMA_11
- S_DMA_55

These signals can be selected as follows:

- When the UARTi.UART_SCR[0] DMA_MODE_CTL bit is set to 0, setting the UARTi.UART_FCR[3] DMA_MODE_CTL bit to 0 enables DMA mode 0. Setting the DMA_MODE_CTL bit to 1 enables DMA mode 1.
- When the DMA_MODE_CTL bit is set to 1, the UARTi.UART_FCR[2:1] DMA_MODE_2 bit field determines DMA mode 0 to mode 3 based on the supplementary control register (UART_SCR) description.

For example:

- If no DMA operation is desired, set the DMA_MODE_CTL bit to 1 and the DMA_MODE_2 bit field to 0x0. (The DMA_MODE bit is discarded.)
- If DMA mode 1 is desired, set the DMA_MODE_CTL bit to 0 and the DMA_MODE bit to 1, or set the DMA_MODE_CTL bit to 1 and the DMA_MODE_2 bit field to 01. (The DMA_MODE bit is discarded.)

If the FIFOs are disabled (the UARTi.UART_FCR[0] FIFO_EN bit is set to 0), the DMA occurs in single-character transfers.

When DMA mode 0 is programmed, the signals associated with DMA operation are not active.

Depending on UART_MDR3[2] SET_DMA_TX_THRESHOLD, the threshold can be programmed different ways:

- SET_TX_DMA_THRESHOLD = 1:

  The threshold value will be the value of the UART_TX_DMA_THRESHOLD register. If SET_TX_DMA_THRESHOLD + TX trigger spaces 64, then the default method of threshold is used: threshold value = TX FIFO size.
- SET_TX_DMA_THRESHOLD = 0:

Copyright © 2011, Texas Instruments Incorporated

The threshold value = TX FIFO size TX trigger space. The TX DMA line is asserted if the TX FIFO level is lower then the threshold. It remains asserted until TX trigger spaces number of bytes are written into the FIFO. The DMA line is then deasserted and the FIFO level is compared with the threshold value.

18.3.6.4.1 DMA Transfers (DMA Mode 1, 2, or 3)

Figure 18-7 through Figure 18-10 show the supported DMA operations.

Figure 18-7. Receive FIFO DMA Request Generation (32 Characters)

In receive mode, a DMA request is generated when the RX FIFO reaches its threshold level defined in the trigger level register (UARTi.UART_TLR). This request is deasserted when the number of bytes defined by the threshold level is read by the sDMA.

In transmit mode, a DMA request is automatically asserted when the TX FIFO is empty. This request is deasserted when the number of bytes defined by the number of spaces in the UARTi.UART_TLR register is written by the sDMA. If an insufficient number of characters is written, the DMA request stays active.

Figure 18-8. Transmit FIFO DMA Request Generation (56 Spaces)

The DMA request is again asserted if the FIFO can receive the number of bytes defined by the UARTi.UART_TLR register.

Copyright © 2011, Texas Instruments Incorporated

The threshold can be programmed in a number of ways. Figure 18-8 shows a DMA transfer operating with a space setting of 56 that can arise from using the auto settings in the UARTi.UART_FCR[5:4] TX_FIFO_TRIG bit field or the UARTi.UART_TLR[3:0] TX_FIFO_TRIG_DMA bit field concatenated with the TX_FIFO_TRIG bit field.

The setting of 56 spaces in the UART/IrDA/CIR module must correlate with the settings of the sDMA so that the buffer does not overflow (program the DMA request size of the LH controller to equal the number of spaces in the UART/IrDA/CIR module).

Figure 18-9 shows an example with eight spaces to show the buffer level crossing the space threshold. The LH DMA controller settings must correspond to those of the UART/IrDA/CIR module.

Figure 18-9. Transmit FIFO DMA Request Generation (8 Spaces)

The next example shows the setting of one space that uses the DMA for each transfer of one character to the transmit buffer (see Figure 18-10). The buffer is filled faster than the baud rate at which data is transmitted to the TX pin. Eventually, the buffer is completely full and the DMA operations stop transferring data to the transmit buffer.

On two occasions, the buffer holds the maximum amount of data words; shortly after this, the DMA is disabled to show the slower transmission of the data words to the TX pin. Eventually, the buffer is emptied at the rate specified by the baud rate settings of the UARTi.UART_DLL and UARTi.UART_DLH registers.

The DMA settings must correspond to the system LH DMA controller settings to ensure correct operation of this logic.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Figure 18-10. Transmit FIFO DMA Request Generation (1 Space)

The final example shows the setting of eight spaces, but setting the TX DMA threshold directly by setting the UART_MDR3[1] NONDEFAULT_FREQ bit and the UART_TX_DMA_THRESHOLD register (see Figure 18-11). In the example, UART_TX_DMA_THRESHOLD[2:0] TX_DMA_THRESHOLD = 3 and the trigger level is 8. The buffer is filled at a faster rate than the baud rate transmits data to the TX pin. The buffer is filled with 8 bytes and the DMA operations stop transferring data to the transmit buffer. When the buffer is emptied to the threshold level by transmission, the DMA operation activates again to fill the buffer with 8 bytes.

Eventually, the buffer is emptied at the rate specified by the baud rate settings of the UART_DLL and UART_DLH registers.

If the selected threshold level plus the trigger level exceed the maximum buffer size, the original TX DMA threshold method is used to prevent TX overrun, regardless of the value of the UART_MDR3[1] NONDEFAULT_FREQ bit.

The DMA settings must correspond to the settings of the system local host DMA controller to ensure the correct operation of this logic.

Figure 18-11. Transmit FIFO DMA Request Generation Using Direct TX DMA Threshold Programming. (Threshold = 3; Spaces = 8)

18.3.6.4.2 DMA Transmission

Figure 18-12 shows DMA transmission.

Figure 18-12. DMA Transmission

1. Data to be transmitted are put in the device memory reserved for UART/IrDA/CIR transmission by the DMA:
   (a) Until the TX FIFO trigger level is not reached, a DMA request is generated
   (b) An element (1 byte) is transferred from the SDRAM to the TX FIFO at each DMA request (DMA element synchronization).
2. Data in the TX FIFO are automatically transmitted.
3. The end of the transmission is signaled by the UARTi.UART_THR empty (TX FIFO empty).

NOTE: In IrDA mode, the transmission does not end immediately after the TX FIFO empties, at which point the last data byte, the CRC field, and the stop flag still must be transmitted; thus, the end of transmission occurs a few milliseconds after the UARTi.UART_THR register empties.

18.3.6.4.3 DMA Reception

Figure 18-13 shows DMA reception.

Figure 18-13. DMA Reception

1. Enable the reception.
2. Received data are put in the RX FIFO.
3. Data are transferred from the RX FIFO to the device memory by the DMA:
   (a) At each received byte, the RX FIFO trigger level (one character) is reached and a DMA request is generated.
   (b) An element (1 byte) is transferred from the RX FIFO to the SDRAM at each DMA request (DMA element synchronization).
4. The end of the reception is signaled by the EOF interrupt.

18.3.7 Mode Selection

18.3.7.1 Register Access Modes

18.3.7.1.1 Operational Mode and Configuration Modes

Register access depends on the register access mode, although register access modes are not correlated to functional mode selection. Three different modes are available:

- Operational mode
- Configuration mode A
- Configuration mode B

Operational mode is the selected mode when the function is active; serial data transfer can be performed in this mode.

Configuration mode A and configuration mode B are used during module initialization steps. These modes enable access to configuration registers, which are hidden in the operational mode. The modes are used when the module is inactive (no serial data transfer processed) and only for initialization or reconfiguration of the module.

The value of the UARTi.UART_LCR register determines the register access mode (see Table 18-16).

Table 18-16. UART/IrDA/CIR Register Access Mode Programming (Using UART_LCR)

Mode	Condition
Configuration mode A	UART_LCR[7] = 0x1 and UART_LCR[7:0] != 0xBF
Configuration mode B	UART_LCR[7] = 0x1 and UART_LCR[7:0] = 0xBF
Operational mode	UART_LCR[7] = 0x0

18.3.7.1.2 Register Access Submode

In each access register mode (operational mode or configuration mode A/B), some register accesses are conditional on the programming of a submode (MSR_SPR, TCR_TLR, and XOFF). These registers are identified in , *UART/IrDA/CIR Register Manual*.

Table 18-17 through Table 18-19 summarize the register access submodes.

Table 18-17. Subconfiguration Mode A Summary

Mode	Condition
MSR_SPR	(UART_EFR[4] = 0x0 or UART_MCR[6] = 0x0)
TCR_TLR	UART_EFR[4] = 0x1 and UART_MCR[6] = 0x1

Table 18-18. Subconfiguration Mode B Summary

Mode	Condition
TCR_TLR	UART_EFR[4] = 0x1 and UART_MCR[6] = 0x1
XOFF	(UART_EFR[4] = 0x0 or UART_MCR[6] = 0x0)

Table 18-19. Suboperational Mode Summary

Mode	Condition
MSR_SPR	UART_EFR[4] = 0x0 or UART_MCR[6] = 0x0
TCR_TLR	UART_EFR[4] = 0x1 and UART_MCR[6] = 0x1

18.3.7.1.3 Registers Available for the Register Access Modes

Table 18-20 lists the names of the register bits in each access register mode. Gray shading indicates that the register does not depend on the register access mode (available in all modes).

Table 18-20. UART/IrDA/CIR Register Access Mode Overview

18.3.8 Protocol Formatting

18.3.8.1 UART Mode

18.3.8.1.1 UART Clock Generation: Baud Rate Generation

The UART function contains a programmable baud generator and a set of fixed dividers that divide the 48-MHz clock input down to the expected baud rate.

Figure 18-14 shows the baud rate generator and associated controls.

Figure 18-14. Baud Rate Generation

Copyright © 2011, Texas Instruments Incorporated

CAUTION

Before initializing or modifying clock parameter controls (UARTi.UART_DLH, UARTi.UART_DLL), MODE_SELECT = DISABLE (UARTi.UART_MDR1[2:0]) must be set to 0x7. Failure to observe this rule can result in unpredictable module behavior.

18.3.8.1.2 Choosing the Appropriate Divisor Value

Two divisor values are:

- UART 16x mode: Divisor value = Operating frequency/(16x baud rate)
- UART 13x mode: Divisor value = Operating frequency/(13x baud rate)

Table 18-25 describes the UART baud rate settings.

Table 18-25. UART Baud Rate Settings (48-MHz Clock)

18.3.8.1.3 UART Data Formatting

The UART can use hardware flow control to manage transmission and reception. Hardware flow control significantly reduces software overhead and increases system efficiency by automatically controlling serial data flow using the RTS output and CTS input signals.

The UART is enhanced with the autobauding function. In control mode, autobauding lets the speed, the number of bits per character, and the parity selected be set automatically.

18.3.8.1.3.1 Frame Formatting

When autobauding is not used, frame format attributes must be defined in the UARTi.UART_LCR register.

Character length is specified using the UARTi.UART_LCR[1:0] CHAR_LENGTH bit field.

The number of stop-bits is specified using the UARTi.UART_LCR[2] NB_STOP bit.

The parity bit is programmed using the UARTi.UART_LCR[5:3] PARITY_EN, PARITY_TYPE_1, and PARITY_TYPE_2 bit fields (see Table 18-26).

Table 18-26. UART Parity Bit Encoding

PARITY_EN	PARITY_TYPE_1	PARITY_TYPE_2	Parity
0	N/A	N/A	No parity
1	0	0	Odd parity
1	1	0	Even parity
1	0	1	Forced 1
1	1	1	Forced 0

18.3.8.1.3.2 Hardware Flow Control

Hardware flow control is composed of auto-CTS and auto-RTS. Auto-CTS and auto-RTS can be enabled and disabled independently by programming the UARTi.UART_EFR[7:6] AUTO_CTS_EN and AUTO_RTS_EN bit fields, respectively.

With auto-CTS, uarti_cts must be active before the module can transmit data.

Auto-RTS activates the uarti_rts output only when there is enough room in the RX FIFO to receive data. It deactivates the uarti_rts output when the RX FIFO is sufficiently full. The HALT and RESTORE trigger levels in the UARTi.UART_TCR register determine the levels at which uarti_rts is activated and deactivated.

If auto-CTS and auto-RTS are enabled, data transmission does not occur unless the RX FIFO has empty space. Thus, overrun errors are eliminated during hardware flow control. If auto-CTS and auto-RTS are not enabled, overrun errors occur if the transmit data rate exceeds the RX FIFO latency.

- Auto-RTS:

  Auto-RTS data flow control originates in the receiver block. The RX FIFO trigger levels used in auto-RTS are stored in the UARTi.UART_TCR register. uarti_rts is active if the RX FIFO level is below the HALT trigger level in the UARTi.UART_TCR[3:0] RX_FIFO_TRIG_HALT bit field. When the RX FIFO HALT trigger level is reached, uarti_rts is deasserted. The sending device (for example, another UART) can send an additional byte after the trigger level is reached because it may not recognize the deassertion of RTS until it begins sending the additional byte.

  uarti_rts is automatically reasserted when the RX FIFO reaches the RESUME trigger level programmed by the UARTi.UART_TCR[7:4] RX_FIFO_TRIG_START bit field. This reassertion requests the sending device to resume transmission.

  In this case, uarti_rts is an active-low signal.

- Auto-CTS:

  The transmitter circuitry checks uarti_cts before sending the next data byte. When uarti_cts is active, the transmitter sends the next byte. To stop the transmitter from sending the next byte, uarti_cts must be deasserted before the middle of the last stop-bit currently sent.

  The auto-CTS function reduces interrupts to the host system. When auto-CTS flow control is enabled, the uarti_cts state changes do not have to trigger host interrupts because the device automatically controls its own transmitter. Without auto-CTS, the transmitter sends any data present in the transmit FIFO, and a receiver overrun error can result.

  In this case, uarti_cts is an active-low signal.

18.3.8.1.3.3 Software Flow Control

Software flow control is enabled through the enhanced feature register (UARTi.UART_EFR) and the modem control register (UARTi.UART_MCR). Different combinations of software flow control can be enabled by setting different combinations of the UARTi.UART_EFR[3:0] bit field (see Table 18-27).

Two other enhanced features relate to software flow control:

- XON any function (UARTi.UART_MCR[5]): Operation resumes after receiving any character after the XOFF character is recognized. If special character detect is enabled and special character is received after XOFF1, it does not resume transmission. The special character is stored in the RX FIFO.

Copyright © 2011, Texas Instruments Incorporated

NOTE: The XON-any character is written into the RX FIFO even if it is a software flow character.

- Special character (UARTi.UART_EFR[5]): Incoming data is compared to XOFF2. When the special character is detected, the XOFF interrupt (UARTi.UART_IIR[4]) is set, but it does not halt transmission. The XOFF interrupt is cleared by a read of UARTi.UART_IIR. The special character is transferred to the RX FIFO. Special character does not work with XON2, XOFF2, or sequential XOFFs.

Table 18-27. UART_EFR[3:0] Software Flow Control Options

Bit 3	Bit 2	Bit 1	Bit 0	TX, RX Software Flow Controls
0	0	X	X	No transmit flow control
1	0	X	X	Transmit XON1, XOFF1
0	1	X	X	Transmit XON2, XOFF2
1	1	X	X	Transmit XON1, XON2: XOFF1, XOFF2[(1)]
X	X	0	0	No receive flow control
X	X	1	0	Receiver compares XON1, XOFF1
X	X	0	1	Receiver compares XON2, XOFF2
X	X	1	1	Receiver compares XON1, XON2: XOFF1, XOFF2[(1)]

(1) In these cases, the XON1 and XON2 characters or the XOFF1 and XOFF2 characters must be transmitted/received sequentially with XON1/XOFF1 followed by XON2/XOFF2.
XON1 is defined in the UARTi.UART_XON1_ADDR1[7:0] XON_WORD1 bit field. XON2 is defined in the UARTi.UART_XON2_ADDR2[7:0] XON_WORD2 bit field.
XOFF1 is defined in the UARTi.UART_XOFF1[7:0] XOFF_WORD1 bit field. XOFF2 is defined in the UARTi.UART_XOFF2[7:0] XOFF_WORD2 bit field.

18.3.8.1.3.3.1 Receive (RX)

When software flow control operation is enabled, the UART compares incoming data with XOFF1/2 programmed characters (in certain cases, XOFF1 and XOFF2 must be received sequentially). When the correct XOFF characters are received, transmission stops after transmission of the current character completes. Detection of XOFF also sets the UARTi.UART_IIR[4] bit (if enabled by UARTi.UART_IER[5]) and causes the interrupt line to go low.

To resume transmission, an XON1/2 character must be received (in certain cases, XON1 and XON2 must be received sequentially). When the correct XON characters are received, the UARTi.UART_IIR[4] bit is cleared and the XOFF interrupt disappears.

NOTE: When a parity, framing, or break error occurs while receiving a software flow control character, this character is treated as normal data and is written to the RX FIFO.

When XON-any and special character detect are disabled and software flow control is enabled, no valid XON or XOFF characters are written to the RX FIFO. For example, when UARTi.UART_EFR[1:0] = 0x2, if XON1 and XOFF1 characters are received, they are not written to the RX FIFO.

When pairs of software flow characters are programmed to be received sequentially (UARTi.UART_EFR[1:0] = 0x3), the software flow characters are not written to the RX FIFO if they are received sequentially. However, received XON1/XOFF1 characters must be written to the RX FIFO if the subsequent character is not XON2/XOFF2.

18.3.8.1.3.3.2 Transmit (TX)

Two XOFF1 characters are transmitted when the RX FIFO passes the trigger level programmed by UARTi.UART_TCR[3:0]. As soon as the RX FIFO reaches the trigger level programmed by UARTi.UART_TCR[7:4], two XON1 characters are sent, so the data transfer recovers.

NOTE: If software flow control is disabled after an XOFF character is sent, the module transmits XON characters automatically to enable normal transmission.

Copyright © 2011, Texas Instruments Incorporated

The transmission of XOFF(s)/XON(s) follows the same protocol as transmission of an ordinary byte from the TX FIFO. This means that even if the word length is 5, 6, or 7 characters, the 5, 6, or 7 LSBs of XOFF1/2 and XON1/2 are transmitted. The 5, 6, or 7 bits of a character are seldom transmitted, but this function is included to maintain compatibility with earlier designs.

It is assumed that software flow control and hardware flow control are never enabled simultaneously.

18.3.8.1.3.4 Autobauding Modes

In autobauding mode, the UART can extract transfer characteristics (speed, length, and parity) from an "at" (AT) command (ASCII code). These characteristics are used to receive data after an AT and to send data.

The following AT commands are valid:

AT	DATA	CR
at	DATA	CR
A/		
a/		

A line break during the acquisition of the sequence AT is not recognized, and an echo function is not implemented in hardware.

A/ and a/ are not used to extract characteristics, but they must be recognized because of their special meaning. A/ or a/ is used to instruct the software to repeat the last received AT command; therefore, an a/ always follows an AT, and transfer characteristics are not expected to change between an AT and an a/.

When a valid AT is received, AT and all subsequent data, including the final CR (0x0D), are saved to the RX FIFO. The autobaud state-machine waits for the next valid AT command. If an a/ (A/) is received, the a/ (A/) is saved in the RX FIFO and the state-machine waits for the next valid AT command.

On the first successful detection of the baud rate, the UART activates an interrupt to signify that the AT (upper or lower case) sequence is detected. The UARTi.UART_UASR register reflects the correct settings for the baud rate detected. Interrupt activity can continue in this fashion when a subsequent character is received. Therefore, it is recommended that the software enable the RHR interrupt when using the autobaud mode.

The following settings are detected in autobaud mode with a module clock of 48 MHz:

- Speed:
  - 115.2K baud
  - 57.6K baud
  - 38.4K baud
  - 28.8K baud
  - 19.2K baud
  - 14.4K baud
  - 9.6K baud
  - 4.8K baud
  - 2.4K baud
  - 1.2K baud
- Length: 7 or 8 bits
- Parity: Odd, even, or space

NOTE: The combination of 7-bit character plus space parity is not supported.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Autobauding mode is selected when the UARTi.UART_MDR1[2:0] MODE_SELECT bit field is set to 0x2. In UART autobauding mode, UARTi.UART_DLL, UARTi.UART_DLH, and UARTi.UART_LCR[5:0] bit field settings are not used; instead, UART_UASR is updated with the configuration detected by the autobauding logic.

UART_UASR Autobauding Status Register Use

This register is used to set up transmission according to the characteristics of the previous reception instead of the UARTi.UART_LCR, UARTi.UART_DLL, and UARTi.UART_DLH registers when the UART is in autobauding mode.

To reset the autobauding hardware (to start a new AT detection) or to set the UART in standard mode (no autobaud), the UARTi.UART_MDR1[2:0] MODE_ SELECT bit field must be set to reset state (0x7) and then to the UART in autobauding mode (0x2) or to the UART in standard mode (0x0).

Use limitation:

- Only 7- and 8-bit characters (5- and 6-bit not supported)
- 7-bit character with space parity not supported
- Baud rate between 1200 and 115,200 bps (10 possibilities)

18.3.8.1.3.5 Error Detection

When the UARTi.UART_LSR register is read, the UARTi.UART_LSR[4:2] bit field reflects the error bits (BI: break condition, FE: framing error, PE: parity error) of the character at the top of the RX FIFO (the next character to be read). Therefore, reading the UARTi.UART_LSR register and then reading the UARTi.UART_RHR register identifies errors in a character.

Reading the UARTi.UART_RHR register updates the BI, FE, and PE bits (see Table 18-11 for the UART mode interrupts).

The UARTi.UART_LSR[7] RX_FIFO_STS bit is set when there is an error in the RX FIFO and is cleared only when no errors remain in the RX FIFO.

NOTE: Reading the UARTi.UART_LSR register does not cause an increment of the RX FIFO read pointer. The RX FIFO read pointer is incremented by reading the UARTi.UART_RHR register.

Reading the UARTi.UART_LSR register clears the OE bit if it is set (see Table 18-11 for the UART mode interrupts).

18.3.8.1.3.6 Overrun During Receive

Overrun during receive occurs if the RX state-machine tries to write data into the RX FIFO when it is already full. When overrun occurs, the device interrupts the MPU with the UARTi.UART_IIR[5:1] IT_TYPE bit field set to 0x3 (receiver line status error) and discards the remaining portion of the frame.

Overrun also causes an internal flag to be set, which disables further reception. Before the next frame can be received, the MPU must:

- Reset the RX FIFO.
- Read the UARTi.UART_RESUME register, which clears the internal flag.

18.3.8.1.3.7 Time-Out and Break Conditions

18.3.8.1.3.7.1 Time-Out Counter

An RX idle condition is detected when the receiver line (uarti_rx) is high for a time that equals 4x the programmed word length + 12 bits. uarti_rx is sampled midway through each bit.

For sleep mode, the counter is reset when there is activity on uarti_rx.

For the time-out interrupt, the counter counts only when there is data in the RX FIFO, and the count is reset when there is activity on uarti_rx or when the UARTi.UART_RHR register is read.

Copyright © 2011, Texas Instruments Incorporated

18.3.8.1.3.7.2 Break Condition

When a break condition occurs, uarti_tx is pulled low. A break condition is activated by setting the UARTi.UART_LCR[6] BREAK_EN bit. The break condition is not aligned on word stream (a break condition can occur in the middle of a character). The only way to send a break condition on a full character is:

1. Reset the TX FIFO (if enabled).
2. Wait for the transmit shift register to empty (the UARTi.UART_LSR[6] TX_SR_E bit is set to 1).
3. Take a guard time according to stop-bit definition.
4. Set the BREAK_EN bit to 1.

The break condition is asserted while the BREAK_EN bit is set to 1.

The time-out counter and break condition apply only to UART modem operation and not to IrDA/CIR mode operation.

18.3.8.2 IrDA Mode (UART3 Only)

18.3.8.2.1 IrDA Clock Generation: Baud Generator

The IrDA function contains a programmable baud generator and a set of fixed dividers that divide the 48-MHz clock input down to the expected baud rate.

Figure 18-15 shows the baud rate generator and associated controls.

Figure 18-15. Baud Rate Generator

Copyright © 2011, Texas Instruments Incorporated

CAUTION

Before initializing or modifying clock parameter controls (UARTi.UART_DLH, UARTi.UART_DLL), MODE_SELECT=DISABLE (UARTi.UART_MDR1[2:0]) must be set to 0x7). Failure to observe this rule can result in unpredictable module behavior.

18.3.8.2.2 Choosing the Appropriate Divisor Value

Three divisor values are:

- SIR mode: Divisor value = Operating frequency/(16x baud rate)
- MIR mode: Divisor value = Operating frequency/(41x/42x baud rate)
- FIR mode: Divisor value = None

Table 18-28 lists the IrDA baud rate settings.

Table 18-28. IrDA Baud Rate Settings

Baud Rate	IR Mode	Baud Multiple	Encoding	DLH, DLL (Decimal)	Actual Baud Rate	Error (%)	Source Jitter (%)	Pulse Duration
2.4 kbps	SIR	16x	3/16	1250	2.4 kbps	0	0	78.1 µs
9.6 kbps	SIR	16x	3/16	312	9.6153 kbps	+0.16	0	19.5 µs

(1) Average value

NOTE: Baud rate error and source jitter table values do not include 48-MHz reference clock error and jitter.

18.3.8.2.3 IrDA Data Formatting

The methods described in this section apply to all IrDA modes (SIR, MIR, and FIR).

18.3.8.2.3.1 IR RX Polarity Control

The UART3.UART_MDR2[6] IRRXINVERT bit provides the flexibility to invert the uart3_rx_irrx pin in the UART to ensure that the protocol at the output of the transceiver has the same polarity at module level. By default, the uart3_rx_irrx pin is inverted because most transceivers invert the IR receive pin.

18.3.8.2.3.2 IrDA Reception Control

The module can transmit and receive data, but when the device is transmitting, the IR RX circuitry is automatically disabled by hardware.

Operation of the uart3_rx_irrx input can be disabled by the UART3.UART_ACREG[5] DIS_IR_RX bit.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

18.3.8.2.3.3 IR Address Checking

In all IR modes, when address checking is enabled, only frames intended for the device are written to the RX FIFO. This restriction avoids receiving frames not meant for this device in a multipoint infrared environment. It is possible to program two frame addresses that the UART IrDA receives, with the UART3.UART_XON1_ADDR1[7:0] XON_WORD1 and UART3.UART_XON2_ADDR2[7:0] XON_WORD2 bit fields.

Setting the UART_EFR[0] bit to 1 selects address1 checking. Setting the UART_EFR[1] bit to 1 selects address2 checking. Setting the UART_EFR[1:0] bit field to 0 disables all address checking operations. If both bits are set, the incoming frame is checked for private and public addresses.

If address checking is disabled, all received frames write to the RX FIFO.

18.3.8.2.3.4 Frame Closing

A transmission frame can be terminated in two ways:

- Frame-length method: Set the UART3.UART_MDR1[7] FRAME_END_MODE bit to 0. The MPU writes the value of the frame length to the UART3.UART_TXFLH and UART3.UART_TXFLL registers. The device automatically attaches end flags to the frame when the number of bytes transmitted equals the value of the frame length.
- Set-EOT bit method: Set the FRAME_END_MODE bit to 1. The MPU writes 1 to the UART3.UART_ACREG[0] EOT bit just before it writes the last byte to the TX FIFO. When the MPU writes the last byte to the TX FIFO, the device internally sets the tag bit for that character in the TX FIFO. As the TX state-machine reads data from the TX FIFO, it uses this tag-bit information to attach end flags and correctly terminate the frame.

18.3.8.2.3.5 Store and Controlled Transmission

In store and controlled transmission (SCT) mode, the MPU starts writing data to the TX FIFO. Then, after writing a part of a frame (for a bigger frame) or an entire frame (a small frame; that is, a supervisory frame), the MPU writes 1 to the UART3.UART_ACREG[2] SCTX_EN bit (deferred TX start) to start transmission.

SCT mode is enabled by setting the UART3.UART_MDR1[5] SCT bit to 1. This transmission method differs from normal mode, in which data transmission starts immediately after data is written to the TX FIFO. SCT mode is useful for sending short frames without TX underrun.

18.3.8.2.3.6 Error Detection

When the UART3.UART_LSR register is read, the UART3.UART_LSR[4:2] bit field reflects the error bits [FL, CRC, ABORT] of the frame at the top of the STATUS FIFO (the next frame status to be read).

The error is triggered by an interrupt (for IrDA mode interrupts, see Table 18-12). The STATUS FIFO must be read until empty (a maximum of eight reads is required).

18.3.8.2.3.7 Underrun During Transmission

Underrun during transmission occurs when the TX FIFO is empty before the end of the frame is transmitted. When underrun occurs, the device closes the frame with end flags but attaches an incorrect CRC value. The receiving device detects a CRC error and discards the frame; it can then ask for a retransmission.

Underrun also causes an internal flag to be set, which disables additional transmissions. Before the next frame can be transmitted, the MPU must:

- Reset the TX FIFO.
- Read the UART3.UART_RESUME register, which clears the internal flag.

This function can be disabled by the UART3.UART_ACREG[4] DIS_TX_UNDERRUN bit, compensated by the extension of the stop-bit in transmission if the TX FIFO is empty.

Copyright © 2011, Texas Instruments Incorporated

18.3.8.2.3.8 Overrun During Receive

Overrun during receive for the IrDA mode has the same function as that for the UART mode (see Section 18.3.8.1.3.6, *Overrun During Receive*).

18.3.8.2.3.9 Status FIFO

In IrDA modes, a status FIFO records the received frame status. When a complete frame is received, the length of the frame and the error bits associated with the frame are written to the status FIFO.

Reading the UART3.UART_SFREGH[3:0] MSB and UART3.UART_SFREGL[3:0] (LSB) bit fields obtains the frame length. The frame error status is read in the UART3.UART_SFLSR register. Reading the UART3.UART_SFLSR register increments the status FIFO read pointer. Because the status FIFO is eight entries deep, it can hold the status of eight frames.

The MPU uses the frame-length information to locate the frame boundary in the received frame data. The MPU can screen bad frames using the error status information and can later request the sender to resend only the bad frames.

This status FIFO can be used effectively in DMA mode because the MPU must be interrupted only when the programmed status FIFO trigger level is reached, not each time a frame is received.

18.3.8.2.4 SIR Mode Data Formatting

This section provides specific instructions for SIR mode programming.

18.3.8.2.4.1 Abort Sequence

The transmitter can prematurely close a frame (abort) by sending the sequence 0x7DC1. The abort pattern closes the frame without a CRC field or an ending flag.

A transmission frame can be aborted by setting the UART3.UART_ACREG[1] ABORT_EN bit to 1. When this bit is set to 1, 0x7D and 0xC1 are transmitted and the frame is not terminated with CRC or stop flags.

When a 0x7D character followed immediately by a 0xC1 character is received without transparency, the receiver treats a frame as an aborted frame.

CAUTION

When the TX FIFO is not empty and the UART3.UART_MDR1[5] SCT bit is set to 1, the UART IrDA starts a new transfer with data of a previous frame when the aborted frame is sent. Therefore, the TX FIFO must be reset before sending an aborted frame.

18.3.8.2.4.2 Pulse Shaping

SIR mode supports the 3/16 or the 1.6-µs pulse duration methods in receive and transmit. The UART3.UART_ACREG[7] PULSE_TYPE bit selects the pulse width method in the transmit mode.

18.3.8.2.4.3 SIR Free Format Programming

The SIR FF mode is selected by setting the module in the UART mode (UART3.UART_MDR1[2:0] MODE_SELECT = 0x0) and the UART3.UART_MDR2[3] UART_PULSE bit to 1 to allow pulse shaping.

Because the bit format stays the same, some UART mode configuration registers must be set at specific values:

- UART3.UART_LCR[1:0] CHAR_LENGTH bit field = 0x3 (8 data bits)
- UART3.UART_LCR[2] NB_STOP bit = 0x0 (1 stop-bit)
- UART3.UART_LCR[3] PARITY_EN bit = 0x0 (no parity)

The UART mode interrupts are used for the SIR FF mode, but many are not relevant (XOFF, RTS, CTS, modem status register, etc.).

Copyright © 2011, Texas Instruments Incorporated

18.3.8.2.5 MIR and FIR Mode Data Formatting

This section describes common instructions for FIR and MIR mode programming.

At the end of a frame reception, the MPU reads the line status register (UART3.UART_LSR) to detect errors in the received frame.

When the UART3.UART_MDR1[6] SIP_MODE bit is set to 1, the TX state-machine always sends one SIP at the end of a transmission frame. However, when the SIP_MODE bit is set to 0, SIP transmission depends on the UART3.UART_ACREG[3] SEND_SIP bit.

The MPU can set the SEND_SIP bit at least once every 500 ms. The advantage of this approach over the default approach is that the TX state-machine does not have to send the SIP at the end of each frame, thus reducing the overhead required.

18.3.8.3 CIR Mode (UART3 Only)

18.3.8.3.1 CIR Mode Clock Generation

Depending on the encoding method (variable pulse distance/biphase), the MPU must develop a data structure that combines 1 and 0 with a *t* period to encode the complete frame to transmit. This can then be transmitted to the infrared output with a modulation method, as shown in Figure 18-16.

Figure 18-16. CIR Mode Block Components

Based on the requested modulation frequency, the UART3.UART_CFPS register must be set with the correct dividing value to provide an accurate pulse frequency:

Dividing value = (FCLK/12)/MODfreq

Where:

FCLK = System clock frequency (48 MHz)

12 = Real value of baud multiple

MODfreq = Effective frequency of the modulation (MHz)

Example: For a targeted modulation frequency of 36 kHz, the value of UART_CFPS must be set to 0x7 (decimal), which provides a modulation frequency of 36.04 kHz.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

NOTE: The UART3.UART_CFPS register starts with a reset value of 105 (decimal), which translates to a frequency of 38.1 kHz.

The duty cycle of these pulses is user-defined by the pulse duty register bits in the UART3.UART_MDR2 register. Table 18-29 shows the duty cycle.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Table 18-29. Duty Cycle

UART_MDR2[5:4]	Duty Cycle (High-Level)
00	1/4
01	1/3
10	5/12
11	1/2

18.3.8.3.2 CIR Data Formatting

The methods described in this section apply to all CIR modes.

18.3.8.3.2.1 IR RX Polarity Control

The IR RX polarity control for CIR mode has the same function as that for IrDA mode (see Section 18.3.8.2.3.1, *IR RX Polarity Control*).

18.3.8.3.2.2 CIR Transmission

In transmission, the MPU software must exercise an element of real-time control to transmit data packets, each of which must be emitted at a constant delay from the start-bits of each individual packet. Thus, when sending a series of packets, the packet-to-packet delay must respect a specific delay. Two methods can be used to control this delay:

- Filling the TX FIFO with a number of zero bits that are transmitted with a *t* period
- Using an external system timer to control the delay between each start-of-frame or between the end of a frame and the start of the next one. This can be performed by:
  - Controlling the start of the frame using the UART3.UART_MDR1[5] SCT bit and the UART3.UART_ACREG[2] SCTX_EN bit, depending on the timer status
  - Using the UART3.UART_IIR[5] TX_STATUS_IT interrupt bit to preload the next frame in the TX FIFO and to control the start of the timer (in case of control delay between the end of a frame and the start of the next frame)

18.4 UART/IrDA/CIR Basic Programming Model

18.4.1 UART Programming Model

18.4.1.1 Quick Start

This section describes the procedure for operating the UART with FIFO and DMA or interrupts. This three-part procedure ensures the quick start of the UART. It does not cover every UART feature.

The first programming model covers software reset of the UART. The second programming model describes FIFO and DMA configuration. The last programming model describes protocol, baud rate, and interrupt configuration.

NOTE: Each programming model can be used independently of the other two; for instance, reconfiguring the FIFOs and DMA settings only.

Each programming model can be executed starting from any UART register access mode (register modes, submodes, and other register dependencies). However, if the UART register access mode is known before executing the programming model, some steps that enable or restore register access are optional. For more information, see Section 18.3.7.1, *Register Access Modes*.

18.4.1.1.1 Software Reset

To clear the UART registers, perform the following steps:

1. Initiate a software reset:
   Set the UARTi.UART_SYSC[1] SOFTRESET bit to 1.
2. Wait for the end of the reset operation:
   Poll the UARTi.UART_SYSS[0] RESETDONE bit until it equals 1.

18.4.1.1.2 FIFOs and DMA Settings

To enable and configure the receive and transmit FIFOs and program the DMA mode, perform the following steps:

1. Switch to register configuration mode B to access the UARTi.UART_EFR register:
   (a) Save the current UARTi.UART_LCR register value.
   (b) Set the UARTi.UART_LCR register value to 0x00BF.
2. Enable register submode TCR_TLR to access the UARTi.UART_TLR register (part 1 of 2):
   (a) Save the UARTi.UART_EFR[4] ENHANCED_EN value.
   (b) Set the UARTi.UART_EFR[4] ENHANCED_EN bit to 1.
3. Switch to register configuration mode A to access the UARTi.UART_MCR register:
   Set the UARTi.UART_LCR register value to 0x0080.
4. Enable register submode TCR_TLR to access the UARTi.UART_TLR register (part 2 of 2):
   (a) Save the UARTi.UART_MCR[6] TCR_TLR value.
   (b) Set the UARTi.UART_MCR[6] TCR_TLR bit to 1.
5. Enable the FIFO; load the new FIFO triggers (part 1 of 3) and the new DMA mode (part 1 of 2):
   Set the following bits to the desired values:
   - UARTi.UART_FCR[7:6] RX_FIFO_TRIG
   - UARTi.UART_FCR[5:4] TX_FIFO_TRIG
   - UARTi.UART_FCR[3] DMA_MODE
   - UARTi.UART_FCR[0] FIFO_ENABLE (0: Disable the FIFO; 1: Enable the FIFO)

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

NOTE: The UARTi.UART_FCR register is not readable.

6. Switch to register configuration mode B to access the UARTi.UART_EFR register:
   Set the UARTi.UART_LCR register value to 0x00BF.
7. Load the new FIFO triggers (part 2 of 3):
   Set the following bits to the desired values:
   - UARTi.UART_TLR[7:4] RX_FIFO_TRIG_DMA
   - UARTi.UART_TLR[3:0] TX_FIFO_TRIG_DMA
8. Load the new FIFO triggers (part 3 of 3) and the new DMA mode (part 2 of 2):
   Set the following bits to the desired values:
   - UARTi.UART_SCR[7] RX_TRIG_GRANU1
   - UARTi.UART_SCR[6] TX_TRIG_GRANU1
   - UARTi.UART_SCR[2:1] DMA_MODE_2
   - UARTi.UART_SCR[0] DMA_MODE_CTL
9. Restore the UARTi.UART_EFR[4] ENHANCED_EN value saved in Step 2a.
10. Switch to register configuration mode A to access the UARTi.UART_MCR register:
    Set the UARTi.UART_LCR register value to 0x0080.
11. Restore the UARTi.UART_MCR[6] TCR_TLR value saved in Step 4a.
12. Restore the UARTi.UART_LCR value saved in Step 1a.

Triggers are used to generate interrupt and DMA requests. See Section 18.3.6.1.1, *Transmit FIFO Trigger,* to choose the following values:

- UARTi.UART_FCR[5:4] TX_FIFO_TRIG
- UARTi.UART_TLR[3:0] TX_FIFO_TRIG_DMA
- UARTi.UART_SCR[6] TX_TRIG_GRANU1

Triggers are used to generate interrupt and DMA requests. See Section 18.3.6.1.2, *Receive FIFO Trigger*, to choose the following values:

- UARTi.UART_FCR[7:6] RX_FIFO_TRIG
- UARTi.UART_TLR[7:4] RX_FIFO_TRIG_DMA
- UARTi.UART_SCR[7] RX_TRIG_GRANU1

DMA mode enables DMA requests. See Section 18.3.6.4, *FIFO DMA Mode Operation*, to choose the following values:

- UARTi.UART_FCR[3] DMA_MODE
- UARTi.UART_SCR[2:1] DMA_MODE_2
- UARTi.UART_SCR[0] DMA_MODE_CTL

18.4.1.1.3 Protocol, Baud Rate, and Interrupt Settings

To program the protocol, baud rate, and interrupt settings, perform the following steps:

1. Disable UART to access the UARTi.UART_DLL and UARTi.UART_DLH registers:
   Set the UARTi.UART_MDR1[2:0] MODE_SELECT bit field to 0x7.
2. Switch to register configuration mode B to access the UARTi.UART_EFR register:
   Set the UARTi.UART_LCR register value to 0x00BF.
3. Enable access to the UARTi.UART_IER[7:4] bit field:
   (a) Save the UARTi.UART_EFR[4] ENHANCED_EN value.
   (b) Set the UARTi.UART_EFR[4] ENHANCED_EN bit to 1.
4. Switch to register operational mode to access the UARTi.UART_IER register:
   Set the UARTi.UART_LCR register value to 0x0000.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

5. Clear the UARTi.UART_IER register (set the UARTi.UART_IER[4] SLEEP_MODE bit to 0 to change the UARTi.UART_DLL and UARTi.UART_DLH registers). Set the UARTi.UART_IER register value to 0x0000.
6. Switch to register configuration mode B to access the UARTi.UART_DLL and UARTi.UART_DLH registers:

   Set the UARTi.UART_LCR register value to 0x00BF.
7. Load the new divisor value:

   Set the UARTi.UART_DLL[7:0] CLOCK_LSB and UARTi.UART_DLH[5:0] CLOCK_MSB bit fields to the desired values.
8. Switch to register operational mode to access the UARTi.UART_IER register:

   Set the UARTi.UART_LCR register value to 0x0000.
9. Load the new interrupt configuration (0: Disable the interrupt; 1: Enable the interrupt):

   Set the following bits to the desired values:
   - UARTi.UART_IER[7] CTS_IT
   - UARTi.UART_IER[6] RTS_IT
   - UARTi.UART_IER[5] XOFF_IT
   - UARTi.UART_IER[4] SLEEP_MODE
   - UARTi.UART_IER[3] MODEM_STS_IT
   - UARTi.UART_IER[2] LINE_STS_IT
   - UARTi.UART_IER[1] THR_IT
   - UARTi.UART_IER[0] RHR_IT
10. Switch to register configuration mode B to access the UARTi.UART_EFR register:

    Set the UARTi.UART_LCR register value to 0x00BF.
11. Restore the UARTi.UART_EFR[4] ENHANCED_EN value saved in Step 3a.
12. Load the new protocol formatting (parity, stop-bit, character length) and switch to register operational mode:

    Set the UARTi.UART_LCR[7] DIV_EN bit to 0.

    Set the UARTi.UART_LCR[6] BREAK_EN bit to 0.

    Set the following bits to the desired values:
    - UARTi.UART_LCR[5] PARITY_TYPE_2
    - UARTi.UART_LCR[4] PARITY_TYPE_1
    - UARTi.UART_LCR[3] PARITY_EN
    - UARTi.UART_LCR[2] NB_STOP
    - UARTi.UART_LCR[1:0] CHAR_LENGTH
13. Load the new UART mode:

    Set the UARTi.UART_MDR1[2:0] MODE_SELECT bit field to the desired value.

See Section 18.3.8.1.2, *Choosing the Appropriate Divisor Value*, to choose the following values:

- UARTi.UART_DLL[7:0] CLOCK_LSB
- UARTi.UART_DLH[5:0] CLOCK_MSB
- UARTi.UART_MDR1[2:0] MODE_SELECT

See Section 18.3.8.1.3.1, *Frame Formatting*, to choose the following values:

- UARTi.UART_LCR[5] PARITY_TYPE_2
- UARTi.UART_LCR[4] PARITY_TYPE_1
- UARTi.UART_LCR[3] PARITY_EN
- UARTi.UART_LCR[2] NB_STOP
- UARTi.UART_LCR[1:0] CHAR_LENGTH

18.4.1.2 Hardware and Software Flow Control Configuration

This section describes the programming steps to enable and configure hardware and software flow control. Hardware and software flow control cannot be used at the same time.

NOTE: Each programming model can be executed starting from any UART register access mode (register modes, submodes, and other register dependencies). However, if the UART register access mode is known before executing the programming model, some steps that enable or restore register access are optional. For more information, see Section 18.3.7.1, *Register Access Modes*.

18.4.1.2.1 Hardware Flow Control Configuration

To enable and configure hardware flow control, perform the following steps:

1. Switch to register configuration mode A to access the UARTi.UART_MCR register:
   (a) Save the current UARTi.UART_LCR register value.
   (b) Set the UARTi.UART_LCR register value to 0x0080.
2. Enable register submode TCR_TLR to access the UARTi.UART_TCR register (part 1 of 2):
   (a) Save the UARTi.UART_MCR[6] TCR_TLR value.
   (b) Set the UARTi.UART_MCR[6] TCR_TLR bit to 1.
3. Switch to register configuration mode B to access the UARTi.UART_EFR register:
   Set the UARTi.UART_LCR register value to 0x00BF.
4. Enable register submode TCR_TLR to access the UARTi.UART_TCR register (part 2 of 2):
   (a) Save the UARTi.UART_EFR[4] ENHANCED_EN value.
   (b) Set the UARTi.UART_EFR[4] ENHANCED_EN bit to 1.
5. Load the new start and halt trigger values for hardware flow control:
   Set the following bits to the desired values:
   - UARTi.UART_TCR[7:4] AUTO_RTS_START
   - UARTi.UART_TCR[3:0] AUTO_RTS_HALT
6. Enable or disable receive and transmit hardware flow control mode and restore the UARTi.UART_EFR[4] ENHANCED_EN value saved in Step 4a.
   Set the following bits to the desired values:
   - UARTi.UART_EFR[7] AUTO_CTS_EN (0: Disable; 1: Enable)
   - UARTi.UART_EFR[6] AUTO_RTS_EN (0: Disable; 1: Enable)

   Restore the UARTi.UART_EFR[4] ENHANCED_EN bit to the saved value.
7. Switch to register configuration mode A to access the UARTi.UART_MCR register:
   Set the UARTi.UART_LCR register value to 0x0080.
8. Restore the UARTi.UART_MCR[6] TCR_TLR value saved in Step 2a.
9. Restore the UARTi.UART_LCR value saved in Step 1a.

See Section 18.3.8.1.3.2, *Hardware Flow Control*, to choose the following values:

- UARTi.UART_EFR[7] AUTO_CTS_EN
- UARTi.UART_EFR[6] AUTO_RTS_EN
- UARTi.UART_TCR[7:4] AUTO_RTS_START
- UARTi.UART_TCR[3:0] AUTO_RTS_HALT

18.4.1.2.2 Software Flow Control Configuration

To enable and configure software flow control, perform the following steps:

1. Switch to register configuration mode B to access the UARTi.UART_EFR register.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

(a) Save the current UARTi.UART_LCR register value.

(b) Set the UARTi.UART_LCR register value to 0x00BF.

2. Enable register submode XOFF to access the UARTi.UART_XOFF1 and UARTi.UART_XOFF2 registers:

   (a) Save the UARTi.UART_EFR[4] ENHANCED_EN value.

   (b) Set the UARTi.UART_EFR[4] ENHANCED_EN bit to 0.

3. Load the new software flow control characters:

   Set the following bits to the desired values:

   - UARTi.UART_XON1_ADDR1[7:0] XON_WORD1
   - UARTi.UART_XON2_ADDR2[7:0] XON_WORD2
   - UARTi.UART_XOFF1[7:0] XOFF_WORD1
   - UARTi.UART_XOFF2[7:0] XOFF_WORD2

4. Enable access to the UARTi.UART_MCR[7:5] bit field and enable register submode TCR_TLR to access the UARTi.UART_TCR register (part 1 of 2):

   Set the UARTi.UART_EFR[4] ENHANCED_EN bit to 1.

5. Switch to register configuration mode A to access the UARTi.UART_MCR register:

   Set the UARTi.UART_LCR register value to 0x0080.

6. Enable register submode TCR_TLR to access the UARTi.UART_TCR register (part 2 of 2) and enable or disable XON any function:

   (a) Save the UARTi.UART_MCR[6] TCR_TLR value.

   (b) Set the UARTi.UART_MCR[6] TCR_TLR bit to 1.

   (c) Set the UARTi.UART_MCR[5] XON_EN bit to the desired value (0: Disable; 1: Enable).

7. Switch to register configuration mode B to access the UARTi.UART_EFR register:

   Set the UARTi.UART_LCR register value to 0x00BF.

8. Load the new start and halt trigger values for software flow control:

   Set the following bits to the desired values:

   - UARTi.UART_TCR[7:4] AUTO_RTS_START
   - UARTi.UART_TCR[3:0] AUTO_RTS_HALT

9. Enable or disable special character function and load the new software flow control mode and restore the UARTi.UART_EFR[4] ENHANCED_EN value saved in Step 2a:

   Set the following bits to the desired values:

   - UARTi.UART_EFR[5] SPEC_CHAR (0: Disable; 1: Enable)
   - UARTi.UART_EFR[3:0] SW_FLOW_CONTROL

   Restore the UARTi.UART_EFR[4] ENHANCED_EN bit to the saved value.

10. Switch to register configuration mode A to access the UARTi.UART_MCR register:

    Set the UARTi.UART_LCR register value to 0x0080.

11. Restore the UARTi.UART_MCR[6] TCR_TLR bit value saved in Step 6a.

12. Restore the UARTi.UART_LCR value saved in Step 1a.

See Section 18.3.8.1.3.3, *Software Flow Control*, to choose the following values:

- UARTi.UART_EFR[5] SPEC_CHAR
- UARTi.UART_EFR[3:0] SW_FLOW_CONTROL
- UARTi.UART_TCR[7:4] AUTO_RTS_START
- UARTi.UART_TCR[3:0] AUTO_RTS_HALT
- UARTi.UART_XON1_ADDR1[7:0] XON_WORD1
- UARTi.UART_XON2_ADDR2[7:0] XON_WORD2
- UARTi.UART_XOFF1[7:0] XOFF_WORD1

18.4.2 IrDA Programming Model (UART3 Only)

18.4.2.1 SIR Mode

18.4.2.1.1 Receive

The following programming model explains how to program the module to receive an IrDA frame with parity forced to 1, baud rate = 112.5KB, FIFOs disabled, 2 stop-bits, and 8-bit word length:

1. Disable the UART before accessing the UARTi.UART_DLL and UARTi.UART_DLH registers:
   Set the UARTi.UART_MDR1[2:0] MODE_SELECT bit field to 0x7.
2. Grant access to the UART_DLL and UART_DLH registers (the UART_LCR[7] DIV_EN bit = 1):
   UART3.UART_LCR = 0x80 (Data format is unaffected by the use and settings of the UART3.UART_LCR register in IrDA mode.)
3. Load the new baud rate (115.2 kbps):
   UART3.UART_DLL = 0x1A
   UART3.UART_DLH = 0x00
4. Set SIR mode:
   UART3.UART_MDR1[2:0] MODE_SELECT = 0x1
5. Disable access to the UART_DLL and UART_DLH registers and switch to register operational mode:
   UART3.UART_LCR = 0x00.
6. Optional: Enable the RHR interrupt:
   UART3.UART_IER[0] RHR_IT = 0x1

18.4.2.1.2 Transmit

The following programming model explains how to program the module to transmit an IrDA 6-byte frame with no parity, baud rate = 112.5 kbps, FIFOs disabled, 3/16 encoding, 2 stop-bits, and 7-bit word length:

1. Disable the UART before accessing the UARTi.UART_DLL and UARTi.UART_DLH registers:
   Set the UART_MDR1[2:0] MODE_SELECT bit field to 0x7.
2. Grant access to the UART_EFR register:
   UART3.UART_LCR = 0xBF
3. Enable the enhanced features (the UART_EFR[4] ENAHNCED_EN bit = 1):
   Set the UART3.UART_EFR register value to 0x10.
4. Grant access to the UART_DLL and UART_DLH registers (the UART_LCR[7] DIV_EN bit = 1):
   UART3.UART_LCR = 0x80 (Data format is unaffected by the use and settings of the UART3.UART_LCR register in IrDA mode.)
5. Load the new baud rate (115.2 kbps):
   UART3.UART_DLL = 0x1A
   UART3.UART_DLH = 0x00
6. Set SIR mode (the UART_MDR1[2:0] MODE_SELECT bit field = 0x1):
   UART3.UART_MDR1 = 0x01
7. Disable access to the UART_DLL and UART_DLH registers and switch to register operational mode:
   UART3.UART_LCR = 0x00.
8. Force DTR output to active:
   UART3.UART_MCR[0] DTR = 1
9. Optional: Enable the THR interrupt:
   UART3.UART_IER[1] THR_IT = 1
10. Set transmit frame length to 6 bytes:
    UART3.UART_TXFLL = 0x06
11. Set 7 starts of frame transmission:
    UART3.UART_EBLR = 0x08
12. Optional: Set SIR pulse width to be 1.6 us:
    UART3.UART_ACREG[7] PULSE_TYPE = 1
13. Load the UART_THR register with the data to be transmitted.

Copyright © 2011, Texas Instruments Incorporated

18.4.2.2 MIR Mode

18.4.2.2.1 Receive

The following programming model explains how to program the module to receive an IrDA frame with no parity, baud rate = 1.152 Mpbs, and FIFOs disabled.

1. Disable the UART before accessing the UARTi.UART_DLL and UARTi.UART_DLH registers:
   Set the UARTi.UART_MDR1[2:0] MODE_SELECT bit field to 0x7.
2. Grant access to the UART_DLL and UART_DLH registers (UART_LCR[7] DIV_EN bit = 1):
   UART3.UART_LCR = 0x80 (Data format is unaffected by the use and settings of the UART3.UART_LCR register in IrDA mode.)
3. Load the new baud rate (1.152 Mpbs):
   UART3.UART_DLL = 0x01
   UART3.UART_DLH = 0x00
4. Set MIR mode:
   UART3.UART_MDR1[2:0] MODE_SELECT = 0x4
5. Disable access to the UART_DLL and UART_DLH registers and switch to register operational mode:
   UART3.UART_LCR = 0x00
6. Force DTR output to active (UART_MCR[0] DTR = 1):
   Force RTS output to active (UART_MCR[1] RTS = 1).
   UART3.UART_MCR = 0x3
7. Optional: Enable the RHR interrupt:
   UART3.UART_IER[0] RHR_IT = 1

18.4.2.2.2 Transmit

The following programming model explains how to program the module to transmit an IrDA 60-byte frame with no parity, baud rate = 1.152 Mpbs, and FIFOs disabled:

1. Disable the UART before accessing the UARTi.UART_DLL and UARTi.UART_DLH registers:
   Set the UARTi.UART_MDR1[2:0] MODE_SELECT bit field to 0x7.
2. Grant access to the UART_DLL and UART_DLH registers (UART_LCR[7] DIV_EN bit = 1):
   UART3.UART_LCR = 0x80 (Data format is unaffected by the use and settings of the UART3.UART_LCR register in IrDA mode.)
3. Load the new baud rate (1.152 Mpbs):
   UART3.UART_DLL = 0x01
   UART3.UART_DLH = 0x00
4. Set MIR mode:
   UART3.UART_MDR1[2:0] MODE_SELECT = 0x4
5. Disable access to the UART_DLL and UART_DLH registers and switch to register operational mode:
   UART3.UART_LCR = 0x00
6. Force DTR output to active:
   UART3.UART_MCR[0] DTR = 1
7. Optional: Enable the THR interrupt:
   UART3.UART_IER[1] THR_IT = 1
8. Set the frame length to 60 bytes:
   UART3.UART_TXFLL = 0x3C
9. Optional: Transmit eight additional starts of frame (MIR mode requires two starts):
   UART3.UART_EBLR = 0x08
10. SIP is sent at the end of transmission:
    UART3.UART_ACREG[3] = 1
11. Load the UART_THR register with the data to be transmitted.

18.4.2.3 FIR Mode

18.4.2.3.1 Receive

The following programming model explains how to program the module to receive the IrDA frame with no parity, baud rate = 4 Mbps, FIFOs enabled, 8-bit word length.

1. Disable the UART before accessing the UART3.UART_DLL and UART3.UART_DLH registers:
   Set the UART3.UART_MDR1[2:0] MODE_SELECT bit field to 0x7.
2. Grant access to the UART_DLL and UART_DLH registers (UART_LCR[7] DIV_EN bit = 1):
   UART3.UART_LCR = 0x80 (Data format is unaffected by the use and settings of the UART3.UART_LCR register in IrDA mode.)
3. FIFO clear and enable:
   UART3.UART_FCR = 0x7 (TX/RX FIFO trigger: UART_FCR[7:6] and UART_FCR[5:4])
   UART3.UART_LCR[7] = 0
4. Set FIR mode:
   UART3.UART_MDR1[2:0] MODE_SELECT = 0x5
5. Set frame length:
   UART3.UART_RXFLL = 0xA (Data + CRC + STOP)
6. Disable access to the UART3.UART_DLL registers and UART3.UART_DLH and switch to register operational mode:
   UART3.UART_LCR[7] DIV_EN = 0x0
7. Optional: Enable the RHR interrupt:
   UART3.UART_IER[0] RHR_IT = 1

18.4.2.3.2 Transmit

The following programming model explains how to program the module to transmit an IrDA 4-byte frame with no parity, baud rate = 4 Mbps, FIFOs enabled, and 8-bit word length.

1. Disable the UART before accessing the UART3.UART_DLL and UART3.UART_DLH registers:
   Set the UART3.UART_MDR1[2:0] MODE_SELECT bit field to 0x7.
2. Grant access to EFR_REG:
   UART3.UART_LCR = 0xBF
3. Enable the enhanced features (EFR_REG[4] ENAHNCED_EN = 0x1):
   UART3.UART_EFR = 0x10
4. FIFO clear and enable:
   UART3.UART_FCR = 0x7 (TX/RX FIFO trigger: UART_FCR[7:6] and UART_FCR[5:4]).
   UART3.UART_LCR[7] = 0
5. Set FIR mode and enable auto-SIP mode:
   UART3.UART_MDR1 = 0x45
6. Set frame length:
   UART3.UART_TXFLL = 0x4
   UART3.UART_TXFLH = 0x0
   UART3.UART_RXFLL = 0xA (Data + CRC + STOP)
   UART3.UART_RXFLH = 0x0
7. Force DTR output to active:
   UART3.UART_MCR[0] DTR = 0x1
8. Optional: Enable the THR interrupt:
   UART3.UART_IER[1] THR_IT = 0x1
9. Optional: Transmit eight additional starts of frame (MIR mode requires two starts):
   UART3.UART_EBLR = 0x08
10. SIP is sent at the end of transmission:
    UART3.UART_ACREG[3] = 1
11. Load the UART_THR register with the data to be transmitted.

18.5 UART Registers

Each register is selected using a combination of address and for some LCR register bit(s) setting as shown in Table 18-30. The following registers are accessible by the local host (LH) at address = module base address + address offset. The module base address is the module start address. Note that register address offsets depends upon the module address alignment at the system top level.

Table 18-30. UART Registers

Address Offset	Registers					
	LCR[7] = 0		LCR[7:0] ≠ BFh		LCR[7:0] = BFh	
	Read	Write	Read	Write	Read	Write
0h	RHR	THR	DLL	DLL	DLL	DLL
4h	IER[(1)]	IER[(1)]	DLH	DLH	DLH	DLH
8h	IIR	FCR[(2)]	IIR	FCR[(2)]	EFR	EFR
Ch	LCR	LCR	LCR	LCR	LCR	LCR
10h	MCR[(2)]	MCR[(2)]	MCR[(2)]	MCR[(2)]	XON1/ADDR1	XON1/ADDR1
14h	LSR	-	LSR	-	XON2/ADDR2	XON2/ADDR2
18h	MSR/TCR[(3)]	TCR[(3)]	MSR/TCR[(3)]	TCR[(3)]	XOFF1/TCR[(3)]	XOFF1/TCR[(3)]
1Ch	SPR/TLR[(3)]	SPR/TLR[(3)]	SPR/TLR[(3)]	SPR/TLR[(3)]	XOFF2/TLR[(3)]	XOFF2/TLR[(3)]
20h	MDR1	MDR1	MDR1	MDR1	MDR1	MDR1
24h	MDR2	MDR2	MDR2	MDR2	MDR2	MDR2
28h	SFLSR	TXFLL	SFLSR	TXFLL	SFLSR	TXFLL
2Ch	RESUME	TXFLH	RESUME	TXFLH	RESUME	TXFLH
30h	SFREGL	RXFLL	SFREGL	RXFLL	SFREGL	RXFLL
34h	SFREGH	RXFLH	SFREGH	RXFLH	SFREGH	RXFLH
38h	BLR	BLR	UASR	-	UASR	-
3Ch	ACREG	ACREG	-	-	-	-
40h	SCR	SCR	SCR	SCR	SCR	SCR
44h	SSR	SSR[2]	SSR	SSR[2]	SSR	SSR[2]
48h	EBLR	EBLR	-	-	-	-
50h	MVR	-	MVR	-	MVR	-
54h	SYSC	SYSC	SYSC	SYSC	SYSC	SYSC
58h	SYSS	-	SYSS	-	SYSS	-
5Ch	WER	WER	WER	WER	WER	WER
60h	CFPS	CFPS	CFPS	CFPS	CFPS	CFPS

(1) In UART modes, IER[7:4] can only be written when EFR[4] = 1; in IrDA/CIR modes, EFR[4] has no impact on the access to IER[7:4].
(2) MCR[7:5] and FCR[5:4] can only be written when EFR[4] = 1.
(3) Transmission control register (TCR) and trigger level register (TLR) are accessible only when EFR[4] = 1 and MCR[6] = 1.

18.5.1 Receiver Holding Register (RHR)

The receiver section consists of the receiver holding register and the receiver shift register. The RHR is actually a 64-byte FIFO. The receiver shift register receives serial data from RX input. The data is converted to parallel data and moved to the RHR. If the FIFO is disabled, location zero of the FIFO is used to store the single data character.

NOTE: If an overflow occurs, the data in the RHR is not overwritten.

The receiver holding register (RHR) register is shown in Figure 18-17 and described in Table 18-31.

Figure 18-17. Receiver Holding Register (RHR)

15–8	7–0
Reserved	RHR
R-0	R-unknown

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 18-31. Receiver Holding Register (RHR) Field Descriptions

Bit	Field	Value	Description
15-8	Reserved	0	Reserved.
7-0	RHR	0-FFh	Receive holding register.

18.5.2 Transmit Holding Register (THR)

The transmitter section consists of the transmit holding register and the transmit shift register. The transmit holding register is a 64-byte FIFO. The MPU writes data to the THR. The data is placed in the transmit shift register where it is shifted out serially on the TX output. If the FIFO is disabled, location zero of the FIFO is used to store the data.

The transmit holding register (THR) is shown in Figure 18-18 and described in Table 18-32.

Figure 18-18. Transmit Holding Register (THR)

18.5.3 Interrupt Enable Register (IER) - UART Mode

The interrupt enable register (IER) can be programmed to enable/disable any interrupt. There are seven types of interrupt in this mode: receiver error, RHR interrupt, THR interrupt, XOFF received and $\overline{CTS}$/$\overline{RTS}$ change of state from low to high. Each interrupt can be enabled/disabled individually. There is also a sleep mode enable bit. The UART interrupt enable register (IER) is shown in Figure 18-19 and described in Table 18-33.

Figure 18-19. UART Interrupt Enable Register (IER)

18.5.4 Interrupt Enable Register (IER) - IrDA Mode

The IrDA interrupt enable register (IER) can be programmed to enable/disable any interrupt. There are 8 types of interrupt in these modes, received EOF, LSR interrupt, TX status, status FIFO interrupt, RX overrun, last byte in RX FIFO, THR interrupt, and RHR interrupt. Each interrupt can be enabled/disabled individually. The IrDA interrupt enable register (IER) is shown in Figure 18-20 and described in Table 18-34.

NOTE: The TXSTATUSIT interrupt reflects two possible conditions. The MDR2[0] bit should be read to determine the status in the event of this interrupt.

Figure 18-20. IrDA Interrupt Enable Register (IER)

18.5.5 Interrupt Enable Register (IER) - CIR Mode

The CIR interrupt enable register (IER) can be programmed to enable/disable any interrupt. There are 5 types of interrupt in these modes, TX status, RX overrun, RX stop interrupt, THR interrupt, and RHR interrupt. Each interrupt can be enabled/disabled individually. The CIR interrupt enable register (IER) is shown in Figure 18-21 and described in Table 18-35.

NOTE: In CIR mode, the TXSTATUSIT bit has only one meaning corresponding to the case MDR2[0] = 0.

The RXSTOPIT interrupt is generated based on the value set in the BOF Length register (EBLR).

Figure 18-21. CIR Interrupt Enable Register (IER)

LEGEND: R = Read only; W = Write only; -*n* = value after reset

Table 18-39. FIFO Control Register (FCR) Field Descriptions

Bit	Field	Value	Description
15-8	Reserved	0	Reserved.
7-6	RX_FIFO_TRIG	0-3h	Sets the trigger level for the RX FIFO: If SCR[7] = 0 and TLR[7:4] ≠ 0000, RX_FIFO_TRIG is not considered. If SCR[7] = 1, RX_FIFO_TRIG is 2 LSB of the trigger level (1 to 63 on 6 bits) with the granularity 1. If SCR[7] = 0 and TLR[7:4] = 0000:
		0	8 characters
		1h	16 characters
		2h	56 characters
		3h	60 characters
5-4	TX_FIFO_TRIG	0-3h	Can be written only if EFR[4] = 1. Sets the trigger level for the TX FIFO: If SCR[6] = 0 and TLR[3:0] ≠ 0000, TX_FIFO_TRIG is not considered. If SCR[6] = 1, TX_FIFO_TRIG is 2 LSB of the trigger level (1 to 63 on 6 bits) with a granularity of 1. If SCR[6] = 0 and TLR[3:0] = 0000:
		0	8 characters
		1h	16 characters
		2h	32 characters
		3h	56 characters
3	DMA_MODE		Can be changed only when the baud clock is not running (DLL and DLH cleared to 0). If SCR[0] = 0, this register is considered.
		0	DMA_MODE 0 (No DMA).
		1	DMA_MODE 1 (UART_NDMA_REQ[0] in TX, UART_NDMA_REQ[1] in RX).
2	TX_FIFO_CLEAR	0	No change.
		1	Clears the transmit FIFO and resets its counter logic to 0. Returns to 0 after clearing FIFO.
1	RX_FIFO_CLEAR	0	No change.
		1	Clears the receive FIFO and resets its counter logic to 0. Returns to 0 after clearing FIFO.
0	FIFO_EN		Can be changed only when the baud clock is not running (DLL and DLH cleared to 0).
		0	Disables the transmit and receive FIFOs. The transmit and receive holding registers are 1-byte FIFOs.
		1	Enables the transmit and receive FIFOs. The transmit and receive holding registers are 64-byte FIFOs.

Bit	Field	Value	Description
15-8	Reserved	0	Reserved.
7	DIV_EN		Divisor latch enable.
		0	Normal operating condition.
		1	Divisor latch enable. Allows access to DLL and DLH.
6	BREAK_EN		Break control bit.
			Note: When LCR[6] is set to 1, the TX line is forced to 0 and remains in this state as long as LCR[6] = 1.
		0	Normal operating condition.
		1	Forces the transmitter output to go low to alert the communication terminal.
5	PARITY_TYPE2		If LCR[3] = 1:
		0	If LCR[5] = 0, LCR[4] selects the forced parity format.
		1	If LCR[5] = 1 and LCR[4] = 0, the parity bit is forced to 1 in the transmitted and received data.
		1	If LCR[5] = 1 and LCR[4] = 1, the parity bit is forced to 0 in the transmitted and received data.
4	PARITY_TYPE1		If LCR[3] = 1:
		0	Odd parity is generated.
		1	Even parity is generated.
3	PARITY_EN		Parity bit.
		0	No parity.
		1	A parity bit is generated during transmission, and the receiver checks for received parity.
2	NB_STOP		Specifies the number of stop bits.
		0	1 stop bit (word length = 5, 6, 7, 8).
		1	1.5 stop bits (word length = 5) or 2 stop bits (word length = 6, 7, 8).
1-0	CHAR_LENGTH	0-3h	Specifies the word length to be transmitted or received.
		0	5 bits
		1h	6 bits
		2h	7 bits
		3h	8 bit

R-0	R/W-0	R/W-0	R/W-0	R/W-0	R/W-0	R/W-0	R/W-0

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 18-41. Modem Control Register (MCR) Field Descriptions

Bit	Field	Value	Description
15-7	Reserved	0	Reserved.
6	TCRTLR		Can be written only when EFR[4] = 1.
		0	No action.
		1	Enables access to the TCR and TLR registers.
5	XONEN		Can be written only when EFR[4] = 1.
		0	Disable XON any function.
		1	Enable XON any function.
4	LOOPBACKEN		Loopback mode enable.
		0	Normal operating mode.
		1	Enable local loopback mode (internal). In this mode, the MCR[3:0] signals are looped back into MSR[7:4]. The transmit output is looped back to the receive input internally.
3	CDSTSCH	0	In loopback mode, forces $\overline{DCD}$ input high and IRQ outputs to INACTIVE state.
		1	In loopback mode, forces $\overline{DCD}$ input low and IRQ outputs to INACTIVE state.
2	RISTSCH	0	In loopback mode, forces $\overline{RI}$ input inactive (high).
		1	In loopback mode, forces $\overline{RI}$ input active (low).
1	RTS		In loopback mode, controls MSR[4]. If auto-RTS is enabled, the $\overline{RTS}$ output is controlled by hardware flow control.
		0	Force $\overline{RTS}$ output to inactive (high).
		1	Force $\overline{RTS}$ output to active (low).
0	DTR	0	Force $\overline{DTR}$ output (used in loopback mode) to inactive (high).
		1	Force $\overline{DTR}$ output (used in loopback mode) to active (low).

18.5.12 Line Status Register (LSR) - UART Mode

When the UART line status register (LSR) is read, LSR[4:2] reflect the error bits (BI, FE, PE) of the character at the top of the RX FIFO (next character to be read). Therefore, reading the LSR and then reading the RHR identifies errors in a character. Reading RHR updates BI, FE, and PE. LSR [7] is set when there is an error anywhere in the RX FIFO and is cleared only when there are no more errors remaining in the RX FIFO. The UART line status register (LSR) is shown in Figure 18-28 and described in Table 18-42.

NOTE: Reading the LSR does not cause an increment of the RX FIFO read pointer. The RX FIFO read pointer is incremented by reading the RHR. Reading LSR clears OE if set.

Figure 18-28. UART Line Status Register (LSR)

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 18-42. UART Line Status Register (LSR) Field Descriptions

Bit	Field	Value	Description
15-8	Reserved	0	Reserved.
7	RXFIFOSTS	0	Normal operation.
		1	At least one parity error, framing error, or break indication in the RX FIFO. Bit 7 is cleared when no errors are present in the RX FIFO.
6	TXSRE	0	Transmitter hold (TX FIFO) and shift registers are not empty.
		1	Transmitter hold (TX FIFO) and shift registers are empty.
5	TXFIFOE	0	Transmit hold register (TX FIFO) is not empty.
		1	Transmit hold register (TX FIFO) is empty. The transmission is not necessarily completed.
4	RXBI	0	No break condition.
		1	A break was detected while the data being read from the RX FIFO was being received (RX input was low for one character + 1 bit time frame).
3	RXFE	0	No framing error in data being read from RX FIFO.
		1	Framing error occurred in data being read from RX FIFO (received data did not have a valid stop bit).
2	RXPE	0	No parity error in data being read from RX FIFO.
		1	Parity error in data being read from RX FIFO.
1	RXOE	0	No overrun error.
		1	Overrun error occurred. Set when the character held in the receive shift register is not transferred to the RX FIFO. This case occurs only when receive FIFO is full.
0	RXFIFOE	0	No data in the receive FIFO.
		1	At least one data character in the RX FIFO.

18.5.13 Line Status Register (LSR) - IrDA Mode

When the IrDA line status register (LSR) is read, LSR[4:2] reflect the error bits (FL, CRC, ABORT) of the frame at the top of the status FIFO (next frame status to be read). The IrDA line status register (LSR) is shown in Figure 18-29 and described in Table 18-43.

Figure 18-29. IrDA Line Status Register (LSR)

15							8

Table 18-43. IrDA Line Status Register (LSR) Field Descriptions

Bit	Field	Value	Description
15-8	Reserved	0	Reserved.
7	THR_EMPTY	0	Transmit holding register (TX FIFO) is not empty.
		1	Transmit hold register (TX FIFO) is empty. The transmission is not necessarily completed.
6	STS_FIFO_FULL	0	Status FIFO is not full.
		1	Status FIFO is full.
5	RX_LAST_BYTE	0	The RX FIFO (RHR) does not contain the last byte of the frame to be read.
		1	The RX FIFO (RHR) contains the last byte of the frame to be read. This bit is set to 1 only when the last byte of a frame is available to be read. It is used to determine the frame boundary. It is cleared on a single read of the LSR register.
4	FRAME_TOO_LONG	0	No frame-too-long error in frame.
		1	Frame-too-long error in the frame at the top of the status FIFO (next character to be read). This bit is set to 1 when a frame exceeding the maximum length (set by RXFLH and RXFLL registers) is received. When this error is detected, current frame reception is terminated. Reception is stopped until the next START flag is detected.
3	ABORT	0	No abort pattern error in frame.
		1	Abort pattern received. SIR and MIR: abort pattern. FIR: Illegal symbol.
2	CRC	0	No CRC error in frame.
		1	CRC error in the frame at the top of the status FIFO (next character to be read).
1	STS_FIFO_E	0	Status FIFO is not empty.
		1	Status FIFO is empty.
0	RX_FIFO_E	0	At least one data character in the RX FIFO.
		1	No data in the receive FIFO.

18.5.15 Modem Status Register (MSR)

The modem status register (MSR) provides information about the current state of the control lines from the modem, data set, or peripheral device to the Local Host. It also indicates when a control input from the modem changes state. The modem status register (MSR) is shown in Figure 18-31 and described in Table 18-45.

18.5.16 Transmission Control Register (TCR)

The transmission control register (TCR) stores the receive FIFO threshold levels to start/stop transmission during hardware flow control. The transmission control register (TCR) is shown in Figure 18-32 and described in Table 18-46.

NOTE:

- Trigger levels from 0-60 bytes are available with a granularity of 4.
- Trigger level = 4 × [4-bit register value]
- You must ensure that TCR[3:0] > TCR[7:4], whenever auto-RTS or software flow control is enabled to avoid a misoperation of the device. In FIFO interrupt mode with flow control, you have to also ensure that the trigger level to HALT transmission is greater or equal to receive FIFO trigger level (either TLR[7:4] or FCR[7:6]); otherwise, FIFO operation stalls.
- In FIFO DMA mode with flow control, this concept does not exist because the DMA request is sent each time a byte is received.

Figure 18-32. Transmission Control Register (TCR)

15–8	7–4	3–0

18.5.19 Mode Definition Register 1 (MDR1)

The mode of operation is programmed by writing to MDR1[2:0]; therefore, the mode definition register 1 (MDR1) must be programmed on startup after configuration of the configuration registers (DLL, DLH, and LCR). The value of MDR1[2:0] must not be changed again during normal operation. The mode definition register 1 (MDR1) is shown in Figure 18-35 and described in Table 18-51.

NOTE: If the module is disabled by setting the MODESELECT field to 7h, interrupt requests can still be generated unless disabled through the interrupt enable register (IER). In this case, UART mode interrupts are visible. Reading the interrupt identification register (IIR) shows the UART mode interrupt flags.

18.5.20 Mode Definition Register 2 (MDR2)

The MDR2[0] bit describes the status of the TX status interrupt in IIR[5]. The IRTXUNDERRUN bit must be read after a TX status interrupt occurs. The MDR2[2:1] bits set the trigger level for the frame status FIFO (8 entries) and must be programmed before the mode is programmed in MDR1[2:0]. The mode definition register 2 (MDR2) is shown in Figure 18-36 and described in Table 18-52.

NOTE: The MDR2[6] bit gives the flexibility to invert the RX pin inside the UART module to ensure that the protocol at the input of the transceiver module has the same polarity at module level. By default, the RX pin is inverted because most of transceiver invert the IR receive pin.

18.5.21 Status FIFO Line Status Register (SFLSR)

Reading the status FIFO line status register (SFLSR) effectively reads frame status information from the status FIFO. This register does not physically exist. Reading this register increments the status FIFO read pointer (SFREGL and SFREGH must be read first). The status FIFO line status register (SFLSR) is shown in Figure 18-37 and described in Table 18-53.

NOTE: Top of RX FIFO = Next frame to be read from RX FIFO.

Figure 18-37. Status FIFO Line Status Register (SFLSR)

15–8	7–5	4	3	2	1	0

Bit	Field	Value	Description
15-5	Reserved	0	Reserved.
4	OE_ERROR	0	No error
		1	Overrun error in RX FIFO when frame at top of RX FIFO was received.
3	FRAME_TOO_LONG_ERROR	0	No error
		1	Frame-length too long error in frame at top of RX FIFO.
2	ABORT_DETECT	0	No error
		1	Abort pattern detected in frame at top of RX FIFO.
1	CRC_ERROR	0	No error
		1	CRC error in frame at top of RX FIFO.
0	Reserved	0	Reserved.

18.5.22 RESUME Register

The RESUME register is used to clear internal flags, which halt transmission/reception when an underrun/overrun error occurs. Reading this register resumes the halted operation. This register does not physically exist and always reads as 00. The RESUME register is shown in Figure 18-38 and described in Table 18-54.

18.5.23 Status FIFO Register Low (SFREGL)

The frame lengths of received frames are written into the status FIFO. This information can be read by reading the status FIFO register low (SFREGL) and the status FIFO register high (SFREGH). These registers do not physically exist. The LSBs are read from SFREGL and the MSBs are read from SFREGH. Reading these registers does not alter the status FIFO read pointer. These registers must be read before the pointer is incremented by reading the SFLSR. The status FIFO register low (SFREGL) is shown in Figure 18-39 and described in Table 18-55.

Figure 18-39. Status FIFO Register Low (SFREGL)

7-0	SFREGL	0-FFh	LSB part of the frame length.

18.5.24 Status FIFO Register High (SFREGH)

The frame lengths of received frames are written into the status FIFO. This information can be read by reading the status FIFO register low (SFREGL) and the status FIFO register high (SFREGH). These registers do not physically exist. The LSBs are read from SFREGL and the MSBs are read from SFREGH. Reading these registers does not alter the status FIFO read pointer. These registers must be read before the pointer is incremented by reading the SFLSR. The status FIFO register high (SFREGH) is shown in Figure 18-40 and described in Table 18-56.

18.5.25 BOF Control Register (BLR)

The BLR[6] bit is used to select whether C0h or FFh start patterns are to be used, when multiple start flags are required in SIR mode. If only one start flag is required, this is always C0h. If *n* start flags are required, either (n – 1) C0h or (n –1) FFh flags are sent, followed by a single C0h flag (immediately preceding the first data byte). The BOF control register (BLR) is shown in Figure 18-41 and described in Table 18-57.

Figure 18-41. BOF Control Register (BLR)

18.5.26 Auxiliary Control Register (ACREG)

The auxiliary control register (ACREG) is shown in Figure 18-42 and described in Table 18-58.

NOTE:

- If transmit FIFO is not empty and MDR1[5] = 1, IrDA starts a new transfer with data of previous frame as soon as abort frame has been sent. Therefore, TX FIFO must be reset before sending an abort frame.
- It is recommended to disable TX FIFO underrun capability by masking corresponding underrun interrupt. When disabling underrun by setting ACREG[4] = 1, unknown data is sent over TX line.

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 18-58. Auxiliary Control Register (ACREG) Field Descriptions

Bit	Field	Value	Description
15-8	Reserved	0	Reserved.
7	PULSETYPE		SIR pulse-width select:
		0	3/16 of baud-rate pulse width
		1	1.6 µs
6	SDMOD		Primary output used to configure transceivers. Connected to the SD/MODE input pin of IrDA transceivers.
		0	SD pin is set to high.
		1	SD pin is set to low.
5	DISIRRX		Disable RX input.
		0	Normal operation (RX input automatically disabled during transmit, but enabled outside of transmit operation).
		1	Disables RX input (permanent state; independent of transmit).
4	DISTXUNDERRUN		Disable TX underrun.
		0	Long stop bits cannot be transmitted. TX underrun is enabled.
		1	Long stop bits can be transmitted.
3	SENDSIP		MIR/FIR modes only. Send serial infrared interaction pulse (SIP).
			If this bit is set during an MIR/FIR transmission, the SIP is sent at the end of it. This bit is automatically cleared at the end of the SIP transmission.
		0	No action.
		1	Send SIP pulse.
2	SCTXEN		Store and control TX start. When MDR1[5] = 1 and the LH writes 1 to this bit, the TX state-machine starts frame transmission. This bit is self-clearing.
1	ABORTEN		Frame abort. The LH can intentionally abort transmission of a frame by writing 1 to this bit. Neither the end flag nor the CRC bits are appended to the frame.
0	EOTEN		EOT (end-of-transmission) bit. The LH writes 1 to this bit just before it writes the last byte to the TX FIFO in the set-EOT bit frame-closing method. This bit is automatically cleared when the LH writes to the THR (TX FIFO).

18.5.27 Supplementary Control Register (SCR)

The supplementary control register (SCR) is shown in Figure 18-43 and described in Table 18-59.

NOTE: Bit 4 enables the wake-up interrupt, but this interrupt is not mapped into the IIR register. Therefore, when an interrupt occurs and there is no interrupt pending in the IIR register, the SSR[1] bit must be checked. To clear the wake-up interrupt, bit SCR[4] must be reset to 0.

18.5.29 BOF Length Register (EBLR)

In IrDA SIR operation, the BOF length register (EBLR) specifies the number of BOF + xBOFs to transmit. The value set into this register must consider the BOF character; therefore, to send only one BOF with no XBOF, this register must be set to 1. To send one BOF with *n* XBOFs, this register must be set to *n* + 1. Furthermore, the value 0 sends 1 BOF plus 255 XBOFs.

In IrDA MIR mode, the BOF length register (EBLR) specifies the number of additional start flags (MIR protocol mandates a minimum of 2 start flags).

In CIR mode, the BOF length register (EBLR) specifies the number of consecutive zeros to be received before generating the RXSTOP interrupt (IIR[2]). All the received zeros are stored in the RX FIFO. When the register is cleared to 0, this feature is deactivated and always in reception state, which is disabled by setting the ACREG[5] bit to 1.

The BOF length register (EBLR) is shown in Figure 18-45 and described in Table 18-61.

NOTE: If the RX_STOP interrupt occurs before a byte boundary, the remaining bits of the last byte are filled with zeros and then passed into the RX FIFO.

18.5.31 System Configuration Register (SYSC)

The AUTOIDLE bit controls a power-saving technique to reduce the logic power consumption of the module interface; that is, when the feature is enabled, the interface clock is gated off until the module interface is accessed. When the SOFTRESET bit is set high, it causes a full device reset. The system configuration register (SYSC) is shown in Figure 18-47 and described in Table 18-63.

Figure 18-47. System Configuration Register (SYSC)

18.5.33 Wake-Up Enable Register (WER)

The wake-up enable register (WER) is used to mask and unmask a UART event that subsequently notifies the system. An event is any activity in the logic that can cause an interrupt and/or an activity that requires the system to wake up. Even if wakeup is disabled for certain events, if these events are also an interrupt to the UART, the UART still registers the interrupt as such. The wake-up enable register (WER) is shown in Figure 18-49 and described in Table 18-65.

18.5.34 Carrier Frequency Prescaler Register (CFPS)

Since the consumer IR (CIR) works at modulation rates of 30–56.8 kHz, the 48 MHz clock must be prescaled before the clock can drive the IR logic. The carrier frequency prescaler register (CFPS) sets the divisor rate to give a range to accommodate the remote control requirements in BAUD multiples of 12×. The value of the CFPS at reset is 105 decimal (69h), which equates to a 38.1 kHz output from starting conditions. The 48 MHz carrier is prescaled by the CFPS that is then divided by the 12× BAUD multiple. The carrier frequency prescaler register (CFPS) is shown in Figure 18-50 and described in Table 18-66.

Figure 18-50. Carrier Frequency Prescaler Register (CFPS)

15–8	7–0

18.5.35 Divisor Latches Low Register (DLL)

The divisor latches low register (DLL) with the DLH register stores the 14-bit divisor for generation of the baud clock in the baud rate generator. DLH stores the most-significant part of the divisor, DLL stores the least-significant part of the divisor. The DLL register is shown in Figure 18-51 and described in Table 18-67.

NOTE: DLL and DLH can be written to only before sleep mode is enabled (before IER[4] is set).

18.5.46 UART Autobauding Status Register (UASR)

The UART autobauding status register (UASR) returns the speed, the number of bits by characters, and the type of parity in UART autobauding mode. In autobauding mode, the input frequency of the UART modem must be fixed to 48 MHz. Any other module clock frequency results in incorrect baud rate recognition. The UART autobauding status register (UASR) is shown in Figure 18-62 and described in Table 18-79.

NOTE:

- This register is used to set up transmission according to characteristics of previous reception, instead of LCR, DLL, and DLH registers when UART is in autobauding mode.
- To reset the autobauding hardware (to start a new "AT" detection) or to set the UART in standard mode (no autobaud), MDR1[2:0] must be set to 7h (reset state), then set to 2h (UART in autobaud mode) or cleared to 0 (UART in standard mode).

Usage limitation:

- Only 7 and 8 bits character (5 and 6 bits not supported).
- 7 bits character with space parity not supported.
- Baud rate between 1200 and 115 200 bp/s (10 possibilities).

19.1 DMTimer

19.1.1 Introduction

19.1.1.1 Overview

The timer module contains a free running upward counter with auto reload capability on overflow. The timer counter can be read and written in real-time (while counting). The timer module includes compare logic to allow an interrupt event on a programmable counter matching value.

A dedicated output signal can be pulsed or toggled on overflow and match event. This output offers a timing stamp trigger signal or PWM (pulse-width modulation) signal sources. A dedicated output signal can be used for general purpose PORGPOCFG (directly driven by bit 14 of the TCLR register). A dedicated input signal is used to trigger automatic timer counter capture and interrupt event, on programmable input signal transition type. A programmable clock divider (prescaler) allows reduction of the timer input clock frequency. All internal timer interrupt sources are merged in one module interrupt line and one wake-up line. Each internal interrupt sources can be independently enabled/disabled.

This module is controllable through the OCP peripheral bus.

As two clock domains are managed inside this module, resynchronization is done by special logic between the OCP clock domain and the Timer clock domain. At reset, synchronization logic allows utilization of all ratios between the OCP clock and the Timer clock. A drawback of this mode is that full-resynchronization path is used with access latency performance impact in terms of OCP clock cycles. In order to improve module access latency, and under restricted conditions on clocks ratios, write-posted mode can be used by setting the POSTED bit of the System Control Register (TSCR). Under this mode, write posted mode is enabled, meaning that OCP write command is granted before write process complete in the timer clock domain. This mode allows software to do concurrent writes on Dual Mode timer registers and to observe write process completion (synchronization) at the software level by reading independent write posted status bits in the Write Posted Status Register (TWPS).

19.1.1.2 Features

The timer consists of the following features:

- Counter timer with compare and capture modes
- Auto-reload mode
- Start-stop mode
- Programmable divider clock source
- 16-32 bit addressing
- “On the fly” read/write registers
- Interrupts generated on overflow, compare and capture
- Interrupt enable
- Wake-up enable
- Write posted mode
- Dedicated input trigger for capture mode and dedicated output trigger/PWM signal
- Dedicated output signal for general purpose use PORGPOCFG
- OCP interface compatible

The Timer resolution and interrupt period are dependent on the selected input clock and clock prescale value. Example resolutions for common clock values are shown in Table 19-1.

Table 19-1. Timer Resolution and Maximum Range

Clock	Prescaler	Resolution	Interrupt Period Range
32.768 KHz	1 (min)	31.25 us	31.25 us to ~36h 35m
	256 (max)	8 ms	8 ms to ~391d 22h 48m

Copyright © 2011, Texas Instruments Incorporated

Table 19-1. Timer Resolution and Maximum Range (continued)

Clock	Prescaler	Resolution	Interrupt Period Range
27 MHz	1 (min)	~37 ns	~37 ns to ~159s
	256 (max)	~9.48 us	~19.7 us to ~11h 18m
38.4 MHz	1 (min)	~26 ns	~26 ns to ~112 s
	256 (max)	~6.7 us	~13.3 us to ~7h 5m

19.1.2 Integration

19.1.2.1 Timer Connectivity Attributes

Table 19-2. Timer[2–7] Connectivity Attributes

Attributes	Type
Power Domain	Peripheral Domain
Clock Domain	PD_PER_L4LS_GCLK (OCP) Functional Clocks: PD_PER_TIMER2_GCLK (Timer 2) PD_PER_TIMER3_GCLK (Timer 3) PD_PER_TIMER4_GCLK (Timer 4) PD_PER_TIMER5_GCLK (Timer 5) PD_PER_TIMER6_GCLK (Timer 6) PD_PER_TIMER7_GCLK (Timer 7)
Reset Signals	PER_DOM_RST_N
Idle/Wakeup Signals	Smart Idle
Interrupt Requests	1 per timer module to MPU Subsystem Also to TSC_ADC event capture mux for Timer 4 – Timer7
DMA Requests	None
Physical Address	L4 Peripheral slave port

19.1.2.2 Timer Clock and Reset Management

Each DMTimer[2–7] functional clock is selected within the PRCM using the associated CLKSEL_TIMERx_CLK register from 3 possible sources:

- The 24 MHz (typ) system clock (CLK_M_OSC)
- The PER PLL generated 32.768 KHz clock (CLK_32KHZ)
- The TCLKIN external timer input clock.

19.1.2.3 Timer Clock Signals

Table 19-3. Timer Clock Signals

Clock Signal	Max Freq	Reference / Source	Comments
Timer[2–7] Clock Signals			
PICLKOCP Interface clock	100 MHz	CORE_CLKOUTM4 / 2	pd_per_l4ls_gclk from PRCM
PICLKTIMER Functional clock	25 MHz*	CLK_M_OSC CLK_32KHZ (PER_CLKOUTM2 / 5859.375) TCLKIN	pd_per_timer2_gclk pd_per_timer3_gclk pd_per_timer4_gclk pd_per_timer5_gclk pd_per_timer6_gclk pd_per_timer7_gclk from PRCM

19.1.2.4 Timer Pin List

The timer PIEVENTCAPT input and PORTIMERPWM output signals are muxed onto a single TIMER I/O pad. The pad direction (and hence the pin function) are controlled from within the DMTimer module using the PORGPOCFG signal as an output enable.

19.1.3 Functional Description

19.1.3.1 Functional Description

The general-purpose timer is an upward counter. It supports 3 functional modes:

- Timer mode
- Capture mode
- Compare mode

By default, after core reset, the capture and compare modes are disabled.

19.1.3.1.1 Timer Mode Functionality

The timer is an upward counter that can be started and stopped at any time through the Timer Control Register (TCLR ST bit). The Timer Counter Register (TCRR) can be loaded when stopped or on the fly (while counting). TCRR can be loaded directly by a TCRR Write access with the new timer value. TCRR can also be loaded with the value held in the Timer Load Register TLDR by a trigger register (TTGR) Write access. The TCRR loading is done regardless the TTGR written value. The timer counter register TCRR value can be read when stopped or captured on the fly by a TCRR Read access. The timer is stopped and the counter value is cleared to “0” when the module’s reset is asserted. The timer is maintained in stop after reset is released. When the timer is stopped TCRR is frozen and it can be restarted from the frozen value unless TCRR has been reloaded with a new value.

In the one shot mode (TCLR AR bit = 0), the counter is stopped after counting overflow (counter value remains at zero).

When the auto-reload mode is enabled (TCLR AR bit = 1), the TCRR is reloaded with the Timer Load Register (TLDR) value after a counting overflow.

It is not recommended to put the overflow value (FFFF FFFFh) in TLDR because it can lead to undesired results.

An interrupt can be issued on overflow if the overflow interrupt enable bit is set in the timer Interrupt Enable Register (IRQENABLE_SET OVF_IT_FLAG bit = 1). A dedicated output pin (PORTIMERPWM) is programmed through TCLR (TRG and PT bits) to generate one positive pulse (prescaler duration) or to invert the current value (toggle mode) when an overflow occurs.

Figure 19-2. TCRR Timing Value

19.1.3.1.2 Capture Mode Functionality

The timer value in TCRR can be captured and saved in TCAR1 or TCAR2 function of the mode selected in TCLR through the field CAPT_MODE when a transition is detected on the module input pin (PIEVENTCAPT). The edge detection circuitry monitors transitions on the input pin (PIEVENTCAPT).

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Rising transition, falling transition or both can be selected in TCLR (TCM bit) to trig the timer counter capture. The module sets the IRQSTATUS (TCAR_IT_FLAG bit) when an active transition is detected and at the same time the counter value TCRR is stored in one of the timer capture registers TCAR1 or TCAR2 as follows:

- If TCLR's CAPT_MODE field is 0 then, on the first enabled capture event, the value of the counter register is saved in TCAR1 register and all the next events are ignored (no update on TCAR1 and no interrupt triggering) until the detection logic is reset or the interrupt status register is cleared on TCAR's position writing a 1 in it.
- If TCLR's CAPT_MODE field is 1 then, on the first enabled captured event, the counter value is saved in TCAR1 register and, on the second enabled capture event, the value of the counter register is saved in TCAR2 register. All the other events are ignored (no update on TCAR1/2 and no interrupt triggering) until the detection logic is reset or the interrupt status register is cleared on TCAR's position writing a 1 in it. This mechanism is useful for period calculation of a clock if that clock is connected to the PIEVENTCAPT input pin.

The edge detection logic is reset (a new capture is enabled) when the active capture interrupt is served - TCAR_IT_FLAG bit of IRQSTATUS (previously 1) is cleared. The timer functional clock (input to prescaler) is used to sample the input pin (PIEVENTCAPT). Input negative or positive pulse can be detected when pulse time is above functional clock period. An interrupt can be issued on transition detection if the capture interrupt enable bit is set in the Timer Interrupt Enable Register IRQENABLE_SET (TCAR_IT_FLAG bit).

In Figure 19-3, the TCM value is 01 and CAPT_MODE is 0 - only rising edge of the PIEVENTCAPT will trigger a capture in TCAR and only TCAR1 will update.

In Figure 19-4, the TCM value is 01 and CAPT_MODE is 1 - only rising edge of the PIEVENTCAPT will trigger a capture in TCAR1 on first enabled event and TCAR2 will update on the second enabled event.

Figure 19-3. Capture Wave Example for CAPT_MODE = 0

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Figure 19-4. Capture Wave Example for CAPT_MODE = 1

19.1.3.1.3 Compare Mode Functionality

When Compare Enable TCLR (CE bit) is set to 1, the timer value (TCRR) is permanently compared to the value held in timer match register (TMAR). TMAR value can be loaded at any time (timer counting or stop). When the TCRR and the TMAR values match, an interrupt can be issued if the IRQENABLE_SET (MAT_EN_FLAG bit) is set. The right programming way is to write a compare value in TMAR register before setting TCLR (CE bit) to avoid any unwanted interrupt due to a reset value matching effect.

The dedicated output pin (PORTIMERPWM) can be programmed through TCLR (TRG and PT bits) to generate one positive pulse (TIMER clock duration) or to invert the current value (toggle mode) when an overflow and a match occur.

19.1.3.1.4 Prescaler Functionality

A prescaler counter can be used to divide the timer counter input clock frequency. The prescaler is enabled when TCLR bit 5 is set (PRE). The 2n division ratio value (PTV) can be configured in the TCLR register. The prescaler counter is reset when the timer counter is stopped or reloaded on the fly.

Table 19-5. Prescaler Functionality

Contexts	Prescaler Counter	Timer Counter
Overflow (when Auto-reload on)	Reset	TLDR
TCRR Write	Reset	TCRR
TTGR Write	Reset	TLDR
Stop	Reset	Frozen

19.1.3.1.5 Pulse-Width Modulation

The timer can be configured to provide a programmable pulse-width modulation (PORTIMERPWM) output. The PORTIMERPWM output pin can be configured to toggle on specified event. TCLR (TRG bits) determines on which register value the PORTIMERPWM pin toggles. Either overflow or match can be used to toggle the PORTIMERPWM pin, when a compare condition occurs.

In case of overflow and match mode, the match event will be ignored from the moment the mode was set-up until the first overflow event occurs (see Figure 19-4).

The TCLR (SCPWM bit) can be programmed to set or clear the PORTIMERPWM output signal while the counter is stopped or the triggering is off only. This allows fixing a deterministic state of the output pin when modulation is stopped. The modulation is synchronously stopped when TRG bit is cleared and overflow occurred.

In the following timing diagram, the internal overflow pulse is set each time (FFFF FFFFFh – TLDR + 1) value is reached, and the internal match pulse is set when the counter reaches TMAR register value. According to TCLR (TRG and PT bits) programming value, the timer provides pulse or PWM on the output pin (PORTIMERPWM).

The TLDR and TMAR registers must keep values smaller than the overflow value (FFFF FFFFh) with at least 2 units. In case the PWM trigger events are both overflow and match, the difference between the values kept in TMAR register and the value in TLDR must be at least 2 units. When match event is used the compare mode TCLR (CE) must be set.

In Figure 19-5, TCLR (SCPWM bit) is cleared to 0. In Figure 19-6, TCLR (SCPWM bit) is set to 1.

19.1.3.1.6 Timer Counting Rate

The timer counter is composed of a prescaler stage and a timer counter. Prescaler stage is clocked with the timer clock and acts as a clock divider for the timer counter stage. The ratio can be managed by accessing the ratio definition field of the control register (PTV and PRE of TCLR). See Table 19-6.

The timer rate is defined by:

- The value of the prescaler fields (PRE and PTV of TCLR register)
- The value loaded into the Timer Load Register (TLDR).

Table 19-6. Prescaler Clock Ratios Value

PRE	PTV	Divisor (PS)
0	X	1
1	0	2
1	1	4
1	2	8
1	3	16
1	4	32
1	5	64
1	6	128
1	7	256

The timer rate equation is as follows:

(FFFF FFFFh – TLDR + 1) × timer Clock period × Clock Divider (PS)

With timer Clock period = 1/ timer Clock frequency and PS = 2(PTV + 1).

As an example, if we consider a timer clock input of 32 kHz, with a PRE field equal to 0, the timer output period is:

Table 19-7. Value and Corresponding Interrupt Period

TLDR	Interrupt period
0000 0000h	37 h
FFFF 0000h	2 s
FFFF FFF0h	500 us
FFFF FFFEh	62.5 us

19.1.3.1.7 Dual Mode Timer Under Emulation

During emulation mode (when PINSUSPENDN signal is active), the timer can/cannot continue running according to the value of the EmuFree bit of the timer OCP configuration register (TIOCP_CFG).

If EmuFree is 1, timer execution is not stopped and, regardless of the value of PINSUSPENDN signal, and the interrupt assertion is still generated when overflow is reached.

If EmuFree is 0, counters (prescaler/timer) are frozen and an increment start occurs again as soon as PINSUSPENDN becomes inactive. The asynchronous input pin is internally synchronized on 2 TIMER clock rising edges.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

19.1.3.2 Accessing Registers

All registers are 32-bit wide, accessible via OCP interface with 16-bit or 32-bit OCP access (Read/Write). The 32-bit registers write update in 16 bits access must be LSB16 first and the second write access must be MSB16. For the write operation, the module allows skipping the MSB access if the user does not need to update the 16 MSB bits of the register, but only for the OCP registers (TIDR, TIOCP_CFG, IRQ_EOI, IRQSTATUS_RAW, IRQSTATUS, IRQENABLE_SET, IRQENABLE_CLR, IRQWAKEEN and TSICR). The write operation on any functional register (TCLR, TCRR, TLDR, TTGR and TMAR) must be complete (the MSB must be written even if the MSB data is not used).

19.1.3.2.1 Programming the Timer Registers

The TLDR, TCRR, TCLR, TIOCP_CFG, IRQ_EOI, IRQSTATUS, IRQENABLE_SET, IRQENABLE_CLR, IRQWAKEEN, TTGR, TSICR and TMAR registers write is done synchronously with OCP clock, by the host, using the OCP bus protocol.

19.1.3.2.2 Reading the Timer Registers

The counter register (TCRR) is a 32-bit “atomic datum” and 16-bit capture is done on the 16-bit LSB first to allow atomic LSB16 + MSB16 capture. Atomic capture is also performed for the TCAR1 and TCAR2 registers as they may change due to internal processes. DSP 16 bit accesses can be interleaved with MCU 32 bit accesses.

19.1.3.2.3 OCP Error Generation

The timer module responds with error indication in the following cases:

Error on write transactions

- Assert the PORSRESP = ERR signal in the same cycle as PORSCMDACCEPTED.
- Use the ERR code for PORSRESP during the response phase.

Error on read transactions

- Assert the PORSRESP = ERR signal in the same cycle as PORSCMDACCEPTED.
- Use the ERR code for PORSRESP during the response phase. PORSDATA in this case is not valid.

Table 19-8. OCP Error Reporting

Error Type	Response: SRESP = ERR
Unsupported PIOCPMCMD command	Yes
Address error: Read or write to a non-existing internal address	No
Read to write-only registers and write to read-only registers	No
Unaligned address (PIOCPMADDR ≠ 00) on read/write transaction	Yes
Unsupported PIOCPMBYTEEN on read/write transaction	Yes

NOTE: Byte enable “0000” is a supported byte enable.

19.1.3.3 Posted Mode Selection

A choice between the two synchronization modes will be made taking into account the frequency ratio and the stall periods that can be supported by the system, without impacting the global performance.

The posted mode selection applies only to functional registers that require synchronization on/from timer clock domain. For write operation the registers affected by this posted/non-posted selection are: TCLR, TLDR, TCRR, TTGR and TMAR. For read operation the register affected by this posted/non-posted selection are: TCRR, TCAR1 and TCAR2.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

The OCP clock domain synchronous registers TIDR, TIOCP_CFG, TISTAT, IRQ_EOI,IRQSTATUS,IRQSTATUS_RAW, IRQENABLE_SET, IRQENABLE_CLR, IRQWAKEEN, TWPS and TSICR are not affected by the posted/non-posted mode selection; the write/read operation is effective and acknowledged (command accepted) after one OCP clock cycle from the command assertion.

The configuration posted/non-posted is made by setting the PIFREQRATIO when the module is integrated. The PIFREQRATIO signal should be tied to '1' when the freq (timer) < freq (OCP)/4 frequency, and tied to 0 when it is the opposite frequency ratio. The PIFREQRATIO represent the reset value of the TSICR (POSTED bit). The configuration can be changed (overwritten) by software, writing the TSICR (POSTED bit) register.

The following cases are possible:

- Posted Mode can be used when the functional frequency range is: freq (timer) < freq (OCP)/4.
- Non-Posted Mode can be used regardless of the frequency range. Recommended frequency is: freq (timer) >= freq (OCP)/4.

NOTE: The Non-Posted Mode can be also used when freq (timer) < freq (OCP)/4, but it is recommended to use the Posted Mode. Using Non-Posted Mode will delay the command accept and the transaction latency will be as described in the below chapters. Posted mode offers an OCP interface latency improvement and can be used only if the frequencies respect the freq (timer) < freq (OCP)/4 formula.

19.1.3.4 Write Registers Access

19.1.3.4.1 Write Posted

This mode can be used only if the functional frequency range is freq (timer) < freq (OCP)/4.

This mode is used if TSICR (POSTED bit) is set to 1 in the timer control register.

This mode uses a posted-write scheme to update any internal register. The write transaction is immediately acknowledged on the OCP interface, although the effective write operation will occur later, due to a resynchronisation in the timer clock domain. This has the advantage of not stalling either the interconnect system, or the CPU that requested the write transaction. For each register, a status bit is provided, that is set if there is a pending write access to this register.

In this mode, it is mandatory that the CPU checks the status bit prior to any write access. In case a write is attempted to a register with a previous access pending, the previous access is discarded without notice (this can lead to unexpected results also).

There is one status bit per register, accessible in the Timer Write Posted Status Register. When the timer module operates in this mode, there is an automatic sampling of the current timer counter value, in an OCP-synchronized capture register. Consequently, any read access to the timer counter register does not add any re-synchronization latency; the current value is always available.

A register read following a write posted register (on the same register) is not insured to read the previous write value if the write posted process is not completed. Software synchronization should be used to avoid non-coherent read.

The drawback of this automatic update mechanism is that it assumes a given relationship between the OCP interface frequency and the timer functional frequency.

This posted period is defined as the interval between the posted write access request and the reset of the posted bit in TWPS register, and can be quantified:

T (reset posted max.) = 3 OCP clock + 2.5 TIMER clock

The time when the write accomplishes is:

T (write accomplish) = 1 OCP clock + 2.5 TIMER clock

Copyright © 2011, Texas Instruments Incorporated

19.1.3.4.2 Write Non-Posted

This mode is functional regardless of the ratio between the OCP interface frequency and the functional clock frequency. Recommended functional frequency range is freq (timer) >= freq (OCP)/4.

This mode is used if TSICR (POSTED bit) is cleared to 0 in the timer control register.

This mode uses a non posted-write scheme to update any internal register. That means the write transaction will not be acknowledged on the OCP interface, until the effective write operation occurs, after the resynchronisation in the timer clock domain. The drawback is that both the interconnect system and the CPU are stalled during this period.

- The latency of the interrupt serving is increased, as the interconnect system and CPU are stalled.
- An interconnect logic, including time-out logic to detect erroneous transactions, can generate an unwanted system abort event.

The stall period is defined as the interval between the non-posted write access request and the rise of the command accept signal and can be quantified:

T (stall max.) = 3 OCP clock + 2.5 TIMER clock

The time when the write accomplishes is:

T (write accomplish) = 1 OCP clock + 2.5 TIMER clock

A register read following a write to the same register is always coherent.

19.1.3.5 Read Registers Access

19.1.3.5.1 Read Posted

This mode can be used only if the functional frequency range is freq (timer) < freq (OCP)/4.

This mode is used if TSICR (POSTED bit) is set to 1 in the timer control register.

This mode uses a posted-read scheme, for reading any internal register. The read transaction is immediately acknowledged on the OCP interface, and the value to be read has been previously resynchronised. This has the advantage of not stalling either the interconnect system, or the CPU that requested the read transaction.

19.1.3.5.2 Read Non-Posted

This mode is functional whatever the ratio between the OCP interface frequency and the functional clock frequency. Recommended functional frequency range is freq (timer) >= freq (OCP)/4.

This mode is used if TSICR (POSTED bit) is cleared to 0 in the timer control register.

This mode uses a non posted-read scheme, for reading any internal register. The read transaction will not be acknowledged on the OCP interface, until the effective read operation occurs, after the resynchronisation in the timer clock domain. The drawback is that both the interconnect system and the CPU are stalled during this period.

- The latency of the interrupt serving is increased, as the interconnect system and the CPU are stalled.
- An interconnect system including time-out logic to detect erroneous transactions can generate an unwanted system abort event.

This mode only applies only to three registers: TCRR, TCAR1 and TCAR2, which need resynchronisation from functional to OCP clock domains.

The stall period is defined as the interval between the non-posted read access request and the rise of the command accept signal and can be quantified:

T (stall max.) = 3 OCP clock + 2.5 TIMER clock

The time when the value is sampled is:

T (read sample) = 1 OCP clock + 2.5 TIMER clock

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 19-10. Identification Register (TIDR) Field Descriptions

Bit	Field	Value	Description
31-30	SCHEME	1	Used to distinguish between old scheme and current.
29-28	Reserved	0	Reads return 0
27-16	FUNC	0	Function indicates a software compatible module family. If there is no level of software compatibility a new Func number (and hence REVISION) should be assigned.
15-11	R_RTL	0	RTL Version (R), maintained by IP design owner. RTL follows a numbering such as X.Y.R.Z which are explained in this table. R changes ONLY when: (1) PDS uploads occur which may have been due to spec changes (2) Bug fixes occur (3) Resets to '0' when X or Y changes. Design team has an internal 'Z' (customer invisible) number which increments on every drop that happens due to DV and RTL updates. Z resets to 0 when R increments.
10-8	X_MAJOR	1	Major Revision (X), maintained by IP specification owner. X changes ONLY when: (1) There is a major feature addition. An example would be adding Master Mode to Utopia Level2. The Func field (or Class/Type in old PID format) will remain the same. X does NOT change due to: (1) Bug fixes (2) Change in feature parameters.
7-6	CUSTOM	0	Indicates a special version for a particular device. Consequence of use may avoid use of standard Chip Support Library (CSL) / Drivers.
5-0	Y_MINOR	0	Minor Revision (Y), maintained by IP specification owner. Y changes ONLY when: (1) Features are scaled (up or down). Flexibility exists in that this feature scalability may either be represented in the Y change or a specific register in the IP that indicates which features are exactly available. (2) When feature creeps from Is-Not list to Is list. But this may not be the case once it sees silicon; in which case X will change. Y does NOT change due to: (1) Bug fixes (2) Typos or clarifications (3) major functional/feature change/addition/deletion. Instead these changes may be reflected via R, S, X as applicable. Spec owner maintains a customer-invisible number 'S' which changes due to: (1) Typos/clarifications (2) Bug documentation. Note that this bug is not due to a spec change but due to implementation. Nevertheless, the spec tracks the IP bugs. An RTL release (say for silicon PG1.1) that occurs due to bug fix should document the corresponding spec number (X.Y.S) in its release notes.

Reserved	IDLEMODE	EMUFREE	SOFTRESET
R-0	R/W-0	R/W-0	R/W-0

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 19-11. Timer OCP Configuration Register (TIOCP_CFG) Field Descriptions

Bit	Field	Value	Description
31-4	Reserved	0	Reserved
3-2	IDLEMODE		Power management, req/ack control
		0	Force-idle mode: local target's idle state follows (acknowledges) the system's idle requests unconditionally, i.e. regardless of the IP module's internal requirements. Backup mode, for debug only.
		1h	No-idle mode: local target never enters idle state. Backup mode, for debug only.
		2h	Smart-idle mode: local target's idle state eventually follows (acknowledges) the system's idle requests, depending on the IP module's internal requirements. IP module shall not generate (IRQ- or DMA-request-related) wakeup events.
		3h	Smart-idle wakeup-capable mode: local target's idle state eventually follows (acknowledges) the system's idle requests, depending on the IP module's internal requirements. IP module may generate (IRQ- or DMA-request-related) wakeup events when in idle state. Mode is only relevant if the appropriate IP module "swakeup" output(s) is (are) implemented.
1	EMUFREE		Emulation mode
		0	The timer is frozen in emulation mode (PINSUSPENDN signal active).
		1	The timer runs free, regardless of PINSUSPENDN value.
0	SOFTRESET		Software reset
		R0	Reset done, no pending action
		W0	No action
		R1	Initiate software reset
		W1	Reset ongoing

19.1.5.10 Timer Counter Register (TCRR)

The TCRR register is a 32-bit register, 16-bit addressable. The MCU can perform a 32-bit access or two 16-bit accesses to access the register while the DSP performs 2 consecutive 16-bit transactions. Note that since the OCP clock is completely asynchronous with the timer clock, some synchronization is done in order to make sure that the TCRR value is not read while it is being incremented.

In 16-bit mode the following sequence must be followed to read the TCRR register properly:

- Perform an OCP Read Transaction to Read the lower 16-bit of the TCRR register (offset = 28h). When the TCRR is read and synchronized, the lower 16-bit LSBs are driven onto the output OCP data bus and the upper 16-bit MSBs of the TCRR register are stored in a temporary register.
- Perform an OCP Read Transaction to read the upper 16-bit of the TCRR register (offset = 2Ah). During this Read, the value of the upper 16-bit MSBs that has been temporary register is forwarded onto the output OCP data bus.

So, to read the value of TCRR correctly, the first OCP read access has to be to the lower 16-bit (offset = 28h), followed by OCP read access to the upper 16-bit (offset = 2Ah).

As the TCRR is updated using more sources (shadow_in_tcrr, incremented value of tcrr, TLDR and “0”), a priority order will be defined:

- The first priority is the OCP update
- The second is the reload way (triggered through TTGR reg. or following an auto-reload overflow)
- The third is the one-shot overflow reset to 0
- The last is the incremented value

19.1.5.13 Timer Write Posted Status Register (TWPS)

In posted mode the software must read the pending write status bits (Timer Write Posted Status register bits [4:0]) to insure that following write access will not be discarded due to on going write synchronization process. These bits are automatically cleared by internal logic when the write to the corresponding register is acknowledged.

19.1.5.15 Timer Capture Register (TCAR1)

When the appropriate (rising, falling or both) transition is detected in the edge detection logic the current counter value is stored to the TCAR1 register. Note that since the OCP clock is completely asynchronous with the timer clock, some synchronization is done in order to make sure that the TCAR1 value is not read while it is being updated due to some capture event.

In 16-bit mode the following sequence must be followed to read the TCAR1 register properly:

- Perform an OCP Read Transaction to Read the lower 16-bits of the TCAR1 register.
- Perform an OCP Read Transaction to read the upper 16-bits of the TCAR1 register.

19.1.5.16 Timer Synchronous Interface Control Register (TSICR)

Access to this register is not stalled even if the timer is in non-posted mode configuration. To abort any wrong behavior, software can permanently reset the functional part of the module. Also in case of a wrong hardware PIFREQRATIO tied the POSTED field can be reprogrammed on the fly, so deadlock situation cannot happen.

NOTE: Reset value of POSTED depends on hardware integration module at design time. Software must read POSTED field to get the hardware module configuration.

Figure 19-22. Timer Synchronous Interface Control Register (TSICR)

1	SFT		This bit resets all the function parts of the module. During reads it always returns 0.
		0	Software reset is enabled
		1	Software reset is disabled
0	Reserved	0	Reserved

19.1.5.17 Timer Capture Register (TCAR2)

When the appropriate (rising, falling or both) transition is detected in the edge detection logic and the capture on second event is activated from the control register (TCLR), the current counter value is stored to the TCAR2 register. Note that since the OCP clock is completely asynchronous with the timer clock, some synchronization is done in order to make sure that the TCAR2 value is not read while it is being updated due to some capture event.

In 16-bit mode the following sequence must be followed to read the TCAR2 register properly:

- Perform an OCP Read Transaction to Read the lower 16-bits of the TCAR2 register.
- Perform an OCP Read Transaction to read the upper 16-bits of the TCAR2 register.

19.2 DMTimer 1ms

19.2.1 Introduction

This peripheral is a 32-bit timer offering:

- Counter timer with compare and capture modes
- Auto-reload mode
- Start-stop mode
- Generate 1 ms tick with 32768-Hz functional clock
- Programmable divider clock source
- 16–32 bit addressing
- On-the-fly read/write registers
- Interrupts generated on overflow, compare and capture
- Interrupt enable
- Wake-up enable
- Write posted mode
- Dedicated input trigger for capture mode and dedicated output trigger/PWM signal
- Dedicated output signal for general purpose use PORGPOCFG
- OCP interface compatible

The timer module contains a free running upward counter with auto reload capability on overflow. The timer counter can be read and written on the fly (while counting). The timer module includes compare logic to allow interrupt event on programmable counter matching value.

A dedicated output signal can be pulsed or toggled on overflow and match event. This output offers timing stamp trigger signal or PWM (pulse width modulation) signal sources. A dedicated output signal can be used for general purpose PORGPOCFG (directly driven by the bit 14 of the TCLR register). A dedicated input signal is used to trigger automatic timer counter capture and interrupt event, on programmable input signal transition type. A programmable clock divider (prescaler) allows reduction of the timer input clock frequency. All internal timer interrupt sources are merged in one module interrupt line and one wake-up line. Each internal interrupt sources can be independently enabled/disabled with a dedicated bit of TIER register for the interrupt features and a dedicated bit of TWER for the wake-up.

This module is controllable through the OCP peripheral bus.

As 2 clocks domains are managed inside this module, resynchronization is done by special logic between OCP clock domain and Timer clock domain. At reset, synchronization logic allows utilization of all ratios between OCP clock and Timer clock. Drawback of this mode is that full-resynchronization path is used with access latency performance impact in terms of OCP clock cycles. In order to improve module access latency, and under restricted conditions on clocks ratios (cf. 7.1 Write posted), write-posted mode can be used by setting POSTED bit of System Control register (TSICR). Under this mode, write posted mode is enabled, meaning that OCP write command is granted before write process complete in the timer clock domain. This mode allows software (SW) to do concurrent writes on Dual Mode timer registers and to observe write process completion (synchronization) at SW level by reading independent write posted status bits in the Write Posted Status Register (TWPS).

19.2.2 Integration

19.2.2.1 Timer Connectivity Attributes

Table 19-27. Timer1 Connectivity Attributes

Attributes	Type
Power Domain	Wakeup Domain
Clock Domain	PD_WKUP_L4_WKUP_GCLK (OCP) PD_WKUP_TIMER1_GCLK (Func)
Reset Signals	WKUP_DOM_RST_N
Idle/Wakeup Signals	Smart Idle / Slave Wakeup
Interrupt Requests	1 to Sabertooth, WakeM3
DMA Requests	None
Physical Address	L4 Wakeup slave port

19.2.2.2 Timer Clock and Reset Manangement

The DMTimer1 1ms timer functional clock can be selected from one of five sources using the CLKSEL_TIMER1MS_CLK register in the PRCM:

- The 24 MHz (typ) system clock (CLK_M_OSC)
- The PER PLL generated 32.768 KHz clock (CLK_32KHZ)
- The TCLKIN external timer input clock
- The on-chip ~32.768 KHz oscillator (CLK_RC32K)
- The external 32.768 KHz oscillator/clock (CLK_32K_RTC)

19.2.2.3 Timer Clock Signals

Table 19-28. Timer Clock Signals

Clock Signal	Max Freq	Reference / Source	Comments
Timer1 (1ms) Clock Signals			
PICLKOCP Interface clock	100 MHz	CORE_CLKOUTM4 / 2	pd_wkup_l4_wkup_gclk from PRCM
PICLKTIMER Functional clock	25 MHz[(1)]	CLK_M_OSC CLK_32KHZ (PER_CLKOUTM2 / 5859.375) TCLKIN CLK_RC32K CLK_32K_RTC	pd_wkup_timer1_gclk from PRCM

(1) Max frequency depends on final SOC timing closure when TCLKIN is selected as the clock source. But PICLKTIMER must be less than PICLKOCP/4.

DRAFT ONLY

19.2.3 Functional Description

The general-purpose timer is an upward counter. It supports 3 functional modes:

- Timer mode
- Capture mode
- Compare mode

By default, after core reset, the capture and compare modes are disabled.

19.2.3.1 Timer Mode Functionality

The timer is an upward counter that can be started and stopped at any time through the Timer Control Register (TCLR ST bit). The Timer Counter Register (TCRR) can be loaded when stopped or on the fly (while counting). TCRR can be loaded directly by a TCRR Write access with the new timer value. TCRR can also be loaded with the value held in the Timer Load Register TLDR by a trigger register (TTGR) Write access. The TCRR loading is done regardless the TTGR written value. The timer counter register TCRR value can be read when stopped or captured on the fly by a TCRR Read access. The timer is stopped and the counter value set to “0” when the module’s reset is asserted. The timer is maintained in stop after reset is released. When the timer is stopped TCRR is frozen and it can be restarted from the frozen value unless TCRR has been reloaded with a new value.

In the one shot mode (TCLR AR bit =”0”), the counter is stopped after counting overflow (counter value remains at zero).

When the auto-reload mode is enabled (TCLR AR bit =”1”), the TCRR is reloaded with the Timer Load Register (TLDR) value after a counting overflow.

It is not recommended to put the overflow value (0xFFFFFFFF) in TLDR because it can lead to undesired results.

An interrupt can be issued on overflow if the overflow interrupt enable bit is set in the timer Interrupt Enable Register (TIER OVF_IT_ENA bit =”1”). A dedicated output pin (PORTIMERPWM) is programmed through TCLR (TRG and PT bits) to generate one positive pulse (prescaler duration) or to invert the current value (toggle mode) when an overflow occurs.

Figure 19-25. TCRR Timing Value

19.2.3.1.1 1 ms Tick Generation

To minimize the error between a true 1ms tick and the tick generated by the 32768 Hz timer the sequencing of the sub-1ms periods and the over-1ms periods must be shuffled.

An additional block (1ms block) is used to correct this error.

In this implementation the increment sequencing is automatically managed by the timer to minimize the error. The value of the Timer Positive Increment register (TPIR) and Timer Negative Increment register (TNIR) only need to be defined by the user. Auto adaptation mechanism is used to simplify the programming model.

Figure 19-26. 1 ms Module Block Diagram

The TPIR, TNIR, TCVR and adders Add1..3 are used to define whether next value loaded in the TCRR will be value of the TLDR (sub-period value) or the value of TLDR – 1 (over-period value).

The following table shows the value loaded in TCRR according to the sign of the result of Add1, Add2 and Add3. MSB = ‘0’ means a positive value, MSB = ‘1’ means a negative value.

Table 19-29. Value Loaded in TCRR to Generate 1 ms Tick

Add1 MSB	Add2 MSB	Add3 MSB	TCRR
0	0	0	TLDR
0	0	1	TLDR

Copyright © 2011, Texas Instruments Incorporated

Table 19-29. Value Loaded in TCRR to Generate 1 ms Tick (continued)

Add1 MSB	Add2 MSB	Add3 MSB	TCRR
0	1	0	TLDR
0	1	1	TLDR - 1
1	0	0	N.A.
1	0	1	N.A.
1	1	0	TLDR - 1
1	1	1	TLDR - 1

The values of TPIR and TNIR registers are calculated with formula:

Positive Increment Value = ((INTEGER[Fclk * Ttick] + 1) * 1e6) - (Fclk * Ttick * 1e6)

Negative Increment Value = (INTEGER[Fclk * Ttick] * 1e6) - (Fclk * Ttick * 1e6)

where:

Fclk – clock frequency (KHz)

Ttick – tick period (ms)

The Timer Overflow Counter Register (TOCR) and the Timer Overflow Wrapping Register (TOWR) are used for interrupt filtering. When timer overflows it increments the 24 bit TOCR register. When 24 bit TOCR register values matches the value in the 24 bit TOWR register and timer overflow is asserted, the TOCR is reset and an interrupt is generated to TISR.

With the Conversion block, in reset state (Positive Increment register, Negative Increment register and Counter Value register are all zeroed) the programming model and the behavior of the DMtimer_dmc1ms remain unchanged.

For 1 ms tick with a 32768-Hz clock:

TPIR = 232000

TNIR = -768000

TLDR = 0xFFFFFFE0

NOTE: Any value of the tick period can be generated with appropriate value of the TPIR, TNIR and TLDR registers.

By default the TPIR, TNIR, TCVR, TOCR, TOWR registers and the associated logic are in reset mode (all 0s) and have no action on the programming model of the DMtimer_dmc1ms.

19.2.3.2 Capture Mode Functionality

The timer value in TCRR can be captured and saved in TCAR1 or TCAR2 function of the mode selected in TCLR through the field CAPT_MODE when a transition is detected on the module input pin (PIEVENTCAPT). The edge detection circuitry monitors transitions on the input pin (PIEVENTCAPT).

Rising transition, falling transition or both can be selected in TCLR (TCM bit) to trig the timer counter capture. The module sets the TISR (TCAR_IT_FLAG bit) when an active transition is detected and at the same time the counter value TCRR is stored in one of the timer capture registers TCAR1 or TCAR2 as follows:

- If TCLR's CAPT_MODE field is "0" then, on the first enabled capture event, the value of the counter register is saved in TCAR1 register and all the next events are ignored (no update on TCAR1 and no interrupt triggering) until the detection logic is reset or the interrupt status register is cleared on TCAR's position writing a "1" in it. .
- If TCLR's CAPT_MODE field is "1" then, on the first enabled captured event, the counter value is saved in TCAR1 register and, on the second enabled capture event, the value of the counter register is saved in TCAR2 register. If capture interrupt is enabled, the interrupt will be asserted on the second event capture. All the other events are ignored (no update on TCAR1/2 and no interrupt triggering) until the detection logic is reset or the interrupt status register is cleared on TCAR's position writing a "1" in it. This mechanism is useful for period calculation of a clock if that clock is connected to the

Copyright © 2011, Texas Instruments Incorporated

PIEVENTCAPT input pin.

The edge detection logic is reset (a new capture is enabled) when the active capture interrupt is served - TCAR_IT_FLAG bit of TISR (previously '1') is cleared through a "1" written in it or when the edge detection mode bits TCLR (TCM bit) passed from the No Capture Mode detection to any other modes. The timer functional clock (input to prescaler) is used to sample the input pin (PIEVENTCAPT). Input negative or positive pulse can be detected when pulse time is above functional clock period. An interrupt can be issued on transition detection if the capture interrupt enable bit is set in the Timer Interrupt Enable Register TIER (TCAR_IT_ENA bit).

See the following examples:

In the next wave, the TCM value is "01" and CAPT_MODE is "0"- only rising edge of the PIEVENTCAPT will trigger a capture in TCAR and only TCAR1 will update.

Figure 19-27. Capture Wave Example for CAPT_MODE 0

In the following example, the TCM value is "01" and CAPT_MODE is "1"- only rising edge of the PIEVENTCAPT will trigger a capture in TCAR1 on first enabled event and TCAR2 will update on the second enabled event.

Figure 19-28. Capture Wave Example for CAPT_MODE 1

19.2.3.3 Compare Mode Functionality

When Compare Enable TCLR (CE bit) is set to "1", the timer value (TCRR) is permanently compared to the value held in timer match register (TMAR). TMAR value can be loaded at any time (timer counting or stop). When the TCRR and the TMAR values match, an interrupt can be issued if the TIER (MAT_IT_ENA bit) is set. The right programming way is to write a compare value in TMAR register before setting TCLR (CE bit) to avoid any unwanted interrupt due to a reset value matching effect.

The dedicated output pin (PORTIMERPWM) can be programmed through TCLR (TRG and PT bits) to generate one positive pulse (TIMER clock duration) or to invert the current value (toggle mode) when an overflow and a match occur.

19.2.3.4 Prescaler Functionality

A prescaler counter can be used to divide the timer counter input clock frequency. The prescaler is enabled when TCLR bit 5 is set (PRE). The 2n division ratio value (PTV) can be configured in the TCLR register.

The prescaler counter is reset when the timer counter is stopped or reloaded on the fly.

Table 19-30. Prescaler/Timer Reload Values Versus Contexts

Contexts	Prescaler Counter	Timer Counter
Overflow (when Auto-reload on)	reset	TLDR
TCRR Write	reset	TCRR
TTGR Write	reset	TLDR
Stop	reset	Frozen

19.2.3.5 Pulse-Width Modulation

The timer can be configured to provide a programmable pulse-width modulation (PORTIMERPWM) output. The PORTIMERPWM output pin can be configured to toggle on specified event. TCLR (TRG bits) determines on which register value the PORTIMERPWM pin toggles. Either overflow or match can be used to toggle the PORTIMERPWM pin, when a compare condition occurs.

In case of overflow and match mode, the match event will be ignored from the moment the mode was set-up until the first overflow event occurs

Copyright © 2011, Texas Instruments Incorporated

The TCLR (SCPWM bit) can be programmed to set or clear the PORTIMERPWM output signal while the counter is stopped or the triggering is off only. This allows fixing a deterministic state of the output pin when modulation is stopped. The modulation is synchronously stopped when TRG bit is cleared and overflow occurred.

In the following timing diagram, the internal overflow pulse is set each time (0xFFFF FFFFF – TLDR +1) value is reached, and the internal match pulse is set when the counter reaches TMAR register value. According to TCLR (TRG and PT bits) programming value, the timer provides pulse or PWM on the output pin (PORTIMERPWM).

The TLDR and TMAR registers must keep values smaller than the overflow value (0xFFFFFFFF) with at least 2 units. In case the PWM trigger events are both overflow and match, the difference between the values kept in TMAR register and the value in TLDR must be at least 2 units. When match event is used the compare mode TCLR (CE) must be set.

On the following wave TCLR (SCPWM bit) is set to ‘0’.

Figure 19-29. Timing Diagram of Pulse-Width Modulation, SCPWM Bit = 0

On the next wave TCLR (SCPWM bit) is set to ‘1’.

Figure 19-30. Timing Diagram of Pulse-Width Modulation, SCPWM Bit = 1

19.2.3.6 Timer Interrupt Control

The timer can issue an overflow interrupt, a timer match interrupt and a timer capture interrupt. Each internal interrupt sources can be independently enabled/disabled in the Interrupt Enable Register TIER. When the interrupt event has been issued the associated interrupt status bit is set in the Timer Status Register (TISR). The pending interrupt event is reset when the set status bit is overwritten by a “1” value. Reading the Interrupt Status Register and writing the value back allows fast acknowledge interrupt process.

19.2.3.7 Sleep Mode Request and Acknowledge

Upon a Sleep mode request issued by the host processor (the Idle Request PIOCPMIDLEREQ signal is active), the timer module will go in Sleep mode according to the IdleMode field of the System configuration register (see TIOCP_CFG and Ref. [4]).

If the IdleMode field sets No-Idle mode, the Timer does not go in Sleep mode and the Idle acknowledge signal (POROCPSIDLEACK) is never asserted.

If the IdleMode field sets Force-Idle mode, the timer goes in Sleep mode independently of the internal module state and the Idle acknowledge signal (POROCPSIDLEACK) is unconditionally asserted.

If the IdleMode field sets Smart-Idle mode, the timer module evaluates its internal capability to have the interface/functional clock switched off. Depending on the ClockActivity field setting the timer module evaluates the internal activity and asserts the Idle acknowledge signal (POROCPSIDLEACK), entering in Sleep mode, ready to issue a wake-up request.

The following table describes the Smart Idle behavior according to the clock activity setting:

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Table 19-31. SmartIdle - Clock Activity Field Configuration

Clock Activity	Functional Clock	OCP Clock	Module Behavior
11	ON	ON	The Idle acknowledge signal is asserted when there are no pending activities on the OCP clock domain, without evaluating the pending activities on the functional clock domain. (The module will enter in Sleep mode and if a pending interrupt event is finished during Idle mode the wake-up signal will be asserted).
10	ON	OFF	
01	OFF	ON	The Idle acknowledge signal is asserted when there are no pending activities on the functional and OCP clock domains (Improved latency in assertion of Idle acknowledge). The Wake-up capability of the module is disabled.
00	OFF	OFF	

This wake-up request is effectively sent only if the field ENAWAKEUP of TIOCP_CFG enables the timer wake-up capability. When the system is awaken, the Idle Request signal goes inactive and the wake-up request signal is also de-asserted.

Figure 19-31. Wake-up Request Generation

19.2.3.7.1 Wake-up Line Release

When the host processor receives wake-up request issued by the timer peripheral, the interface clock is re-activated: the host processor deactivates the PIOCPMIDLEREQ, the timer deactivates the POROCPSIDLEACK signal and then the host can read the corresponding bit in TISR to find out which interrupt source has trigged wake-up request. After acknowledging the wake-up request, the processor resets the status bit and releases the interrupt line by writing a ‘1’ in the corresponding bit of the TISR register.

19.2.3.8 Timer Counting Rate

The dmtimer’s counter is composed of a prescaler stage and a timer counter.

Ratio can be managed by accessing the ratio definition field of the control register (PTV and PRE of TCLR).

The timer rate is defined by:

- The value of the prescaler fields (PRE and PTV of TCLR register)
- The value loaded into the Timer Load Register (TLDR).

Table 19-32. Prescaler Clock Ratios Value

PRE	PTV	Divisor (PS)
0	X	1
1	0	2
1	1	4
1	2	8
1	3	16
1	4	32
1	5	64
1	6	128

Copyright © 2011, Texas Instruments Incorporated

Table 19-32. Prescaler Clock Ratios Value (continued)

PRE	PTV	Divisor (PS)
1	7	256

The timer rate equation is as follows:

(0xFFFF FFFF – TLDR + 1) x timer Clock period x Clock Divider (PS)

With timer Clock period = 1/ timer Clock frequency and PS = 2(PTV + 1).

As example, if we consider a timer clock input of 32 KHz, with a PRE field equals to “0”, the timer output period is:

Table 19-33. Value and Corresponding Interrupt Period

TLDR	Interrupt Period
0x0000 0000	37 h
0xFFFF 0000	2 s
0xFFFF FFF0	500 us
0xFFFF FFFE	62.5 us

19.2.3.9 Dual Mode Timer Under Emulation

During emulation mode (when PINSUSPENDN signal is active), the timer can/cannot continue running according to the value of the EmuFree bit of the timer OCP configuration register (TIOCP_CFG).

If EmuFree is 1, timer execution is not stopped and, regardless of the value of PINSUSPENDN signal, and the interrupt assertion is still generated when overflow is reached.

If EmuFree is 0, counters (prescaler/timer) are frozen and an increment start occurs again as soon as PINSUSPENDN becomes inactive. The asynchronous input pin is internally synchronized on 2 TIMER clock rising edges.

19.2.4 Use Cases

19.2.5 DMTIMER_1MS Registers

Table 19-34 lists the memory-mapped registers for the DMTIMER_1MS. See your device-specific data manual for the memory address of these registers. All other register offset addresses not listed in Table 19-34 should be considered as reserved locations and the register contents should not be modified.

Table 19-34. DMTIMER_1MS REGISTERS

Offset	Acronym	Register Description	Section
0h	TIDR	This register contains the IP revision code	Section 19.2.5.1
10h	TIOCP_CFG	This register controls the various parameters of the OCP interface	Section 19.2.5.2
14h	TISTAT	This register provides status information about the module, excluding the interrupt status information	Section 19.2.5.3
18h	TISR	The Timer Status Register is used to determine which of the timer events requested an interrupt.	Section 19.2.5.4

19.2.5.10 TTGR Register (offset = 30h) [reset = FFFFFFFFh]

This register triggers a counter reload of timer by writing any value in it.

TTGR is shown in Figure 19-41 and described in Table 19-44.

Figure 19-41. TTGR Register

LEGEND: R/W = Read/Write; R = Read only; W1toCl = Write 1 to clear bit; -*n* = value after reset

Table 19-44. TTGR Register Field Descriptions

Bit	Field	Type	Reset	Description
31-0	TTGR_VALUE	R/W	FFFFFFFFh	The value of the trigger register During reads, it always returns "0xFFFFFFFF"

19.2.5.11 TWPS Register (offset = 34h) [reset = 0h]

This register contains the write posting bits for all writ-able functional registers

TWPS is shown in Figure 19-42 and described in Table 19-45.

Figure 19-42. TWPS Register

LEGEND: R/W = Read/Write; R = Read only; W1toCl = Write 1 to clear bit; *-n* = value after reset

Table 19-45. TWPS Register Field Descriptions

Bit	Field	Type	Reset	Description
31-10	Reserved	R	0h	Reads return 0
9	W_PEND_TOWR	R	0h	Write pending for register TOWR 0 - OWR_nPend: No Overflow Wrapping Register write pending. 1 - OWR_Pend: Overflow Wrapping Register write pending.
8	W_PEND_TOCR	R	0h	Write pending for register TOCR 0 - OCR_nPend: No Overflow Counter Register write pending. 1 - OCR_Pend: Overflow Counter Register write pending.
7	W_PEND_TCVR	R	0h	Write pending for register TCVR 0 - CVR_nPend: No Counter Register write pending. 1 - CVR_Pend: Counter Register write pending.
6	W_PEND_TNIR	R	0h	Write pending for register TNIR 0 - NIR_nPend: No Negativ Increment Register write pending. 1 - NIR_Pend: Negativ Increment Register write pending.
5	W_PEND_TPIR	R	0h	Write pending for register TPIR 0 - PIR_nPend: No Positive Increment Register write pending. 1 - PIR_Pend: Positive Increment Register write pending.
4	W_PEND_TMAR	R	0h	Write pending for register TMAR 0 - MAR_nPend: No Match Register write pending 1 - MAR_Pend: Match Register write pending
3	W_PEND_TTGR	R	0h	Write pending for register TTGR 0 - TGR_nPend: No Trigger Register write pending 1 - TGR_Pend: Trigger Register write pending
2	W_PEND_TLDR	R	0h	Write pending for register TLDR 0 - LDR_nPend: No Load Register write pending 1 - LDR_Pend: Load Register write pending
1	W_PEND_TCRR	R	0h	Write pending for register TCRR 0 - CRR_nPend: No Counter Register write pending 1 - CRR_Pend: Counter Register write pending
0	W_PEND_TCLR	R	0h	Write pending for register TCLR 0 - CLR_nPend: No Control Register write pending 1 - CLR_Pend: Control Register write pending

19.3 RTC_SS

19.3.1 Introduction

The real-time clock is a precise timer which can generate interrupts on intervals specified by the user. Interrupts can occur every second, minute, hour, or day. The clock itself can track the passage of real time for durations of several years, provided it has a sufficient power source the whole time.

The basic purpose for the RTC is to keep time of day. The other equally important purpose of RTC is for Digital Rights management. Some degree of tamper proofing is needed to ensure that simply stopping, resetting, or corrupting the RTC does not go unnoticed so that if this occurs, the application can re-acquire the time of day from a trusted source. The final purpose of RTC is to wake the rest of chip up from a power down state.

Alarms are available to interrupt the CPU at a particular time, or at periodic time intervals, such as once per minute or once per day. In addition, the RTC can interrupt the CPU every time the calendar and time registers are updated, or at programmable periodic intervals.

19.3.1.1 Features

The real-time clock (RTC) provides the following features:

- 100-year calendar (xx00 to xx99)
- Counts seconds, minutes, hours, day of the week, date, month, and year with leap year compensation
- Binary-coded-decimal (BCD) representation of time, calendar, and alarm
- 12-hour clock mode (with AM and PM) or 24-hour clock mode
- Alarm interrupt
- Periodic interrupt
- Single interrupt to the CPU
- Supports external 32.768-kHz crystal or external clock source of the same frequency

19.3.1.2 Unsupported RTC Features

This device supports only a single RTC external wake-up event.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

19.3.2 Integration

This device includes a Real-Time Clock Subsystem (RTCSS) module to allow easy tracking of time and date and the generation of real time alarms.

19.3.2.1 RTC Connectivity Attributes

The general connectivity for the RTC module in the device is shown in Table 19-55.

Table 19-55. RTC Module Connectivity Attributes

Attributes	Type
Power Domain	RTC
Clock Domain	PD_RTC_L4_RTC_GCLK (OCP) PD_RTC_RTC32KCLK (Func) CLK_32K_RTC (Func)
Reset Signals	RTC_DOM_RST_N
Idle/Wakeup Signals	Smart Idle
Interrupt Requests	4 Interrupts Alarm interrupt to Sabertooth & WakeM3 Timer interrupt to Sabertooth and WakeM3 Alarm wakeup to WakeM3 Timer wakeup to WakeM3
DMA Requests	None
Physical Address	L4 Wakeup slave port

19.3.2.2 RTC Clock and Reset Management

The RTC functional clock (c32khz_clk input) is sourced by default from the CLK32_KHZ clock derived from the Peripheral PLL. It can also be sourced from the 32-KHz oscillator through a clock mux within and controlled by the RTC_SS.

Table 19-56. RTC Clock Signals

Clock Signal	Max Freq	Reference / Source	Comments
ocp_clk (Interface clock)	100 MHz	CORE_CLKOUTM4 / 2	pd_rtc_l4_rtc_gclk From PRCM
rtc_32K_clk_rtc_32k_clk (Oscillator functional clock)	32.768 KHz	OSC1 In	CLK_32K_RTC From OSC1 In
rtc_32k_clk_rtc_32k_aux_clk (Internal functional clock)	32.768 KHz	PER_CLKOUTM2 / 5859.3752	pd_rtc_rtc_32kclk From PRCM

19.3.2.3 RTC Pin List

The RTC module does not include any external interface pins.

Table 19-57. RTC Pin List

Pin	Type	Description
RTC_PORz	I	RTC Power On Reset
EXT_WAKEUP[3:0]	I	External wakeup
PMIC_POWER_EN	O	Power enable control for external power management IC
Analog Signals		
ENZ_KALDO_1P8V	I	Enable1.8V LDO
VDDS18_RTC	P	1.8V Voltage Supply

19.3.3 Functional Description

This section defines the module interrupt capabilities and requirements.

19.3.3.1 Functional Block Diagram

Figure 19-52 shows the RTC module block diagram. Figure 19-53 shows a functional block diagram of the RTC.

Figure 19-52. RTC Block Diagram

Figure 19-53. RTC Functional Block Diagram

19.3.3.2 Clock Source

The clock reference for the RTC is an internal 32.768-kHz crystal or an external clock source of the same frequency. The source for the RTC reference clock may be provided by a crystal or by an external clock source. The RTC has an internal oscillator buffer to support direct operation with a crystal. The crystal is connected between pins RTC_XI and RTC_XO. RTC_XI is the input to the on-chip oscillator and RTC_XO is the output from the oscillator back to the crystal. For more information about the RTC crystal connection, see your device-specific data manual.

An external 32.768-kHz clock source may be used instead of a crystal. In such a case, the clock source is connected to RTC_XI, and RTC_XO is left unconnected.

If the RTC is not used, the RTC_XI pin should be held low and RTC_XO should be left unconnected. The RTC_disable bit in the control register (CTRL_REG) can be set to save power; however, the RTC_disable bit should not be cleared once it has been set. If the application requires the RTC module to stop and continue, the STOP_RTC bit in CTRL should be used instead.

19.3.3.3 Signal Descriptions

Table 19-58 lists the signals and their descriptions for the RTC.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Table 19-58. RTC Signals

Signal	I/O	Description
RTC_XI	I	RTC time base input signal. RTC_XI can either be driven with a 32.768-kHz reference clock, or RTC_XI and RTC_XO can be connected to an external crystal. This signal is the input to the RTC internal oscillator.
RTC_XO	O	RTC time base output signal. RTC_XO is the output from the RTC internal oscillator. If a crystal is not used as the time base for RTC_XI, RTC_XO should be left unconnected.

19.3.3.4 Interrupt Support

19.3.3.4.1 CPU Interrupts

The RTC generates two interrupt outputs:

- timer_intr is a timer interrupt.
- alarm_intr is an alarm interrupt.

NOTE: Both interrupt outputs support high-level and high-pulse.

19.3.3.4.2 Interrupt Description

19.3.3.4.2.1 Timer Interrupt (timer_intr)

The timer interrupt can be generated periodically: every second, every minute, every hour, or every day (see INTERRUPTS_REG[1:0] for a description of how to set this up). The IT_TIMER bit of the interrupt register enables this interrupt. The timer interrupt is active-low.

The RTC_STATUS_REG[5:2] are only updated at each new interrupt and occur according to Table 19-59. For example, bit 2 (SEC) will always be set when one second has passed. It will also be set when one minute has passed since the completion of one minute also marks the completion of one second (from 59 seconds to 60 seconds). The same holds true for hours and days: each of them will also correspond to the passing of a second.

Conversely, bit 5 (DAY) will always be set when a day has passed. It might also be set when an hour, minute, or second has passed. However, this only occurs when the elapsed hour, minute, or second corresponds to the start of a new day.

Table 19-59. Interrupt Trigger Events

	One day has passed	One hour has passed	One minute has passed	One second has passed
STATUS_REG[5] (DAY)	1	0/1 (1)	0/1 (1)	0/1 (1)
STATUS_REG[4] (HOUR)	1	1	0/1 (1)	0/1 (1)
STATUS_REG[3] (MIN)	1	1	1	0/1 (1)
STATUS_REG[2] (SEC)	1	1	1	1

(1) This event is only triggered when the elapsed time unit (for example, Day) corresponds to the passage of another unit (for example, Seconds). For example, when the clock ticks from 00:23:59:59 (days : hours : minutes : seconds) to 01:00:00:00.

19.3.3.4.2.2 Alarm Interrupt (alarm_intr)

The alarm interrupt can be generated when the time set into TC ALARM registers is exactly the same as in the TC registers. This interrupt is then generated if the IT_ALARM bit of the interrupts register is set. This interrupt is low-level sensitive. RTC_STATUS_REG[6] indicates that IRQ_ALARM_CHIP has occurred. This interrupt is disabled by writing ‘1’ into the RTC_STATUS_REG[6].

To set up an alarm:

- Modify the ALARM_SECONDS, ALARM_MINUTES, ALARM_HOURS, ALARM_DAY, ALARM_WEEK, ALARM_MONTH, and ALARM_YEAR registers to the exact time you want an alarm to generate.
- Set the IT_ALARM bit in the RTC_INTERRUPTS register to enable the alarm interrupt.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

19.3.3.5 Programming/Usage Guide

19.3.3.5.1 Time/Calendar Data Format

The time and calendar data in the RTC is stored as binary-coded decimal (BCD) format. In BCD format, the decimal numbers 0 through 9 are encoded with their binary equivalent. Although most of the time/calendar registers have 4 bits assigned to each BCD digit, some of the register fields are shorter since the range of valid numbers may be limited. For example, only 3 bits are required to represent the day of the week (WEEKS_REG) since only BCD numbers 1 through 7 are required. The following time and calendar registers are supported (BCD Format):

Note that the ALARM registers which share the names above also share the same BCD formatting.

- SECOND - Second Count (00-59)
- MINUTE - Minute Count (00-59)
- HOUR - Hour Count (12HR: 01-12; 24HR: 00-23)
- DAY - Day of the Month Count (01-31)
- WEEK - Day of the Week (0-6: SUN = 0)
- MONTH - Month Count (01-12; JAN = 1)
- YEAR - Year Count (00-99)

19.3.3.5.2 Register Access

The three register types are as follows and each has its own access constraints:

- TC and TC alarm registers
- General registers
- Compensation registers

19.3.3.5.3 OCP MMR Spurious WRT Protection

The module also contains a kicker mechanism (Figure 19-54) to prevent any spurious writes from changing the register values. This mechanism requires two MMR writes to the Kick0 and Kick1 registers with exact data values before the kicker lock mechanism is released. Once released, the MMRs are writeable. The Kick0 data is 83E7 0B13h; the Kick1 data is 95A4 F1E0h. Note that it remains in an unlocked state until an OCP reset or invalid data pattern is written to one of the Kick0 or Kick1 registers.

Figure 19-54. Kick Register State Machine Diagram

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

- S0 is the Reset/Idle state
- S1 is an OCP wrt cycle of 83E7 0B13h at Kick0 completed state
- S2 is the UNLOCK MMR WRT state
- S0 -> S1 when OCP wrt cycle of 83E7 0B13h at Kick0
- S1 -> S2 when OCP wrt cycle of 95A4 F1E0h at Kick1
- S1 -> S0 when OCP reset event
- S2 -> S0 when OCP reset event OR OCP wrt cycle of NOT 83E7 0B13h at Kick0 OR OCP wrt cycle at Kick1
- S2 ->S1 when OCP wrt cycle of 83E7 0B13h at Kick0

19.3.3.5.4 Reading the Timer/Calendar (TC) Registers

The TC registers have a read-show register. The reading of the Seconds register will update all of the TC registers. For example, the Year will only get updated on a reading of the Seconds register. The time/calendar registers are updated every second as the time changes. During a read of the SECONDS register, the RTC copies the current values of the time/date registers into shadow read registers. This isolation assures that the CPU can capture all the time/date values at the moment of the SECONDS read request and not be subject to changing register values from time updates.

If desired, the RTC also provides a one-time-triggered minute-rounding feature to round the MINUTE:SECOND registers to the nearest minute (with zero seconds). This feature is enabled by setting the ROUND_30S bit in the control register (CTRL); the RTC automatically rounds the time values to the nearest minute upon the next read of the SECONDS register.

NOTE: Software should always read the Seconds register first. However, the software does not have to poll any status bit to determine when to read the TC registers. Table 19-60 defines the TC set that gets shadowed.

Table 19-60. RTC Register Names and Values

Time Unit	Range	Remarks
Year	00 to 99	
Month	01 to 12	
Day	01 to 31	Months 1, 3, 5, 7, 8, 10, 12
	01 to 30	Months 4, 6, 9, 11
	01 to 29	Month 2 (leap year)
	01 to 28	Month 2 (common year)
Week	00 to 06	Day of week
Hour	00 to 23	24 hour mode
	01 to 12	AM/PM mode
Minute	00 to 59	
Seconds	00 to 59	

19.3.3.5.4.1 Rounding Seconds

Time can be rounded to the closest minute, by setting the ROUND_30S bit of the control register. When this bit is set, TC values are set to the closest minute value at the next second. The ROUND_30S bit will be automatically cleared when rounding time is performed.

Example:

- If current time is 10H59M45S, round operation will change time to 11H00M00S.
- If current time is 10H59M29S, round operation will change time to 10H59M00S.

Copyright © 2011, Texas Instruments Incorporated

19.3.3.5.5 Modifying the TC Registers

To write correct data from/to the TC and TC alarm registers and read the TC alarm registers, the ARM must first read the BUSY bit of the STATUS register until BUSY is equal to zero. Once the BUSY flag is zero, there is a 15 µs access period in which the ARM can program the TC and TC alarm registers. Once the 15 µs access period passes, the BUSY flag has to be read again from the STATUS register as described previously. If the ARM accesses the TC registers outside of the access period, then the access is not guaranteed.

The ARM can access the STATUS_REG and CTRL_REG at any time, with the exception of CTRL_REG[5] which can only be changed when the RTC is stopped. The ARM can stop the RTC by clearing the STOP_RTC bit of the control register. After clearing this bit, the RUN bit in the STATUS_REG (bit 1) needs to be checked to verify the RTC has in fact stopped. Once this is confirmed, the TC values can be updated. After the values have been updated, the RTC can be re-started by resetting the STOP_RTC bit.

NOTE: After writing to a TC register, the user must wait 4 OCP clock cycles before reading the value from the register. If this wait time is not observed and the TC register is accessed, then old data will be read from the register.

CAUTION

In order to remove any possibility of interrupting the register's read process, thus introducing a potential risk of violating the authorized 15-microsecond access period, it is strongly recommended that you disable all incoming interrupts during the register read process.

Figure 19-55. Flow Control for Updating RTC Registers

19.3.3.5.5.1 General Registers

The ARM can access the STATUS_REG and the CTRL_REG at any time (except the CTRL_REG[5] bit which must be changed only when the RTC is stopped). For the INTERRUPTS_REG, the ARM should respect the available access period to prevent spurious interrupt.

Copyright © 2011, Texas Instruments Incorporated

The RTC_DISABLE bit of the CTRL register must only be used to completely disable the RTC function. When this bit is set, the 32 kHz clock is gated, and the RTC is frozen. From this point, resetting this bit to zero can lead to unexpected behavior. In order to save power, this bit should only be used if the RTC function is unwanted in the application.

19.3.3.5.6 Crystal Compensation

To compensate for any inaccuracy of the 32 kHz oscillator, the ARM can perform a calibration of the oscillator frequency, calculate the drift compensation versus one-hour period, and load the compensation registers with the drift compensation value. Auto compensation is enabled by AUTO_COMP_EN bit in the RTC_CTRL register. If the COMP_REG value is positive, compensation occurs after the second change event. COMP_REG cycles are removed from the next second. If the COMP_REG value is negative, compensation occurs before the second change event. COMP_REG cycles are added to the current second. This enables compensation with a 1 32-kHz period accuracy each hour. The waveform below summarizes positive and negative compensation effect.

Access to the COMP_MSB_REG and COMP_LSB_REG registers must respect the available access period. These registers should not be updated during compensation (first second of each hour), but it is alright to update them during the second preceding a compensation event. For example, the ARM could load the compensation value into these registers after each hour event, during an available access period.

Figure 19-56. Compensation Illustration

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

19.3.3.6 Scratch Registers

The RTC provides three general-purpose registers (SCRATCHx_REG) that can be used to store 32-bit words -- these registers have no functional purpose for the RTC. Software using the RTC may find the SCRATCHx registers to be useful in indicating RTC states. For example, the SCRATCHx_REG registers may be used to indicate write-protection lock status or unintentional power downs. To indicate write-protection, the software should write a unique value to one of the SCRATCHx_REG registers when write-protection is disabled and another unique value when write-protection is enabled again. In this way, the lock-status of the registers can be determined quickly by reading the SCRATCH register. To indicate unintentional power downs, the software should write a unique value to one of the SCRATCHx_REG registers when RTC is configured and enabled. If the RTC is unintentionally powered down, the value written to the SCRATCH register is cleared. For more information, see the registers section.

19.3.3.7 Power Management

The RTC supports the power idle protocol. It has two SWakeup ports: one for the alarm event and one for a timer event.

When the RTC is in IDLE mode, the OCP clock is turned off and the 32 kHz clock remains on. The time and calendar continue to count in IDLE mode. When the RTC is placed back in FUNCTIONAL mode, the TC registers can be read.

The Alarm SWakeup event can be used to wakeup the RTC when it is in IDLE state. In order to do so, the alarm needs to be set and enabled before RTC enters the IDLE state. Once this is done, the SWakeup will occur when the alarm event triggers.

NOTE: Since SWakeup is not periodic, using it to wake up the RTC when in IDLE state is not recommended. Please use Alarm SWakeup instead.

19.3.3.8 Reset Considerations

When the device is initially powered on, the RTC may issue spurious interrupt signals to the CPU. To avoid issues, a software reset should be performed on the RTC module before the CPU interrupt controller is initialized. Also, see the register summary table in the registers section for reset states of each register.

19.3.5.1 Seconds Register (SECONDS_REG)

The SECONDS_REG is used to program the required seconds value of the current time. Seconds are stored as BCD format. In BCD format, the decimal numbers 0 through 9 are encoded with their binary equivalent. If the seconds value is 45, then the value of SEC0 is 5 and value of SEC1 is 4.

19.3.5.2 Minutes Register (MINUTES_REG)

The MINUTES_REG is used to program the minutes value of the current time. Minutes are stored as BCD format. In BCD format, the decimal numbers 0 through 9 are encoded with their binary equivalent. If the minutes value is 32, then the value of MIN0 is 2 and value of MIN1 is 3.

19.3.5.3 Hours Register (HOURS_REG)

The HOURS_REG is used to program the hours value of the current time. Hours are stored as BCD format. In BCD format, the decimal numbers 0 through 9 are encoded with their binary equivalent. In 24Hr time mode if you want to set the hour as 18, then HOUR0 is set as 8 and HOUR1 is set as 1.

19.3.5.4 Days of the Month Register (DAYS_REG)

The DAYS_REG is used to program the day of the month value of the current date. Days are stored as BCD format. In BCD format, the decimal numbers 0 through 9 are encoded with their binary equivalent. If the day value of the date is 28, DAY0 is set as 8 and DAY1 is set as 2.

19.3.5.5 Month Register (MONTHS_REG)

The MONTHS_REG is used to set the month in the year value of the current date. Months are stored as BCD format. In BCD format, the decimal numbers 0 through 9 are encoded with their binary equivalent.

NOTE: Usual notation is taken for month value:

- 01 => January
- 02 => February
- ...
- 12 => December

19.3.5.6 Year Register (YEARS_REG)

The YEARS_REG is used to program the year value of the current date. The year value is represented by only the last 2 digits and is stored as BCD format. In BCD format, the decimal numbers 0 through 9 are encoded with their binary equivalent. The year 1979 is programmed as 79 with YEAR0 set as 9 and YEAR1 set as 7.

19.3.5.7 Day of the Week Register (WEEKS_REG)

The WEEKS_REG is used to program the day of the week value of the current date. The day of the week is stored as BCD format. In BCD format, the decimal numbers 0 through 9 are encoded with their binary equivalent.

NOTE: Sunday is treated as 0, Monday 1, and ending at Saturday with 6.

6	RTC_disable		Disable RTC module and gate 32-kHz reference clock.
		0	RTC enable
		1	RTC disable (no 32 kHz clock)
5	SET_32_COUNTER		Set the 32-kHz counter with the value stored in the compensation registers when the SET_32_COUNTER bit is set.
		0	No action.
		1	Set the 32Khz counter with compensation registers value
4	TEST_MODE		Test mode.
		0	Functional mode
		1	Test mode (Auto compensation is enabled when the 32Khz counter reaches its end)
3	MODE_12_24		Enable 12-hour mode for HOURS and ALARMHOURS registers.
		0	24-hr mode
		1	12-hour mode
2	AUTO_COMP		Enable oscillator compensation mode.
		0	No auto compensation
		1	Auto compensation enabled
1	ROUND_30S		Enable one-time rounding to nearest minute on next time register read.
		0	No update
		1	Time is rounded to the nearest minute
0	STOP_RTC		Stop the RTC 32-kHz counter.
		0	RTC is frozen
		1	RTC is running

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

NOTE:

- The SET_32_counter must only be used when the RTC is frozen.
- The RTC_DISABLE bit of the CTRL register must only be used to completely disable the RTC function. When this bit is set, the 32 kHz clock is gated, and the RTC is frozen. From this point, resetting this bit to zero can lead to unexpected behavior. This bit should only be used if the RTC function is unwanted in the application, in order to save power.
- MODE_12_24: It is possible to switch between the two modes at any time without disturbing the RTC; read or write is always performed with the current mode.
- Auto compensation is enabled by AUTO_COMP_EN bit in the RTC_CTRL register. If the COMP_REG value is positive, compensation occurs after the second change event. COMP_REG cycles are removed from the next second. If the COMP_REG value is negative, compensation occurs before the second change event. COMP_REG cycles are added to the current second. This enables it to compensate with one 32-kHz period accuracy each hour.
- ROUND_30S is a toggle bit; ARM can only write 1 and RTC clears it. If the ARM sets the ROUND_30S bit and then reads it, the ARM read 1 until the round-to-the-closet-minute is performed at the next second.
- ARM can stop the RTC by clearing STOP_RTC bit of the control register (owing to internal resynchronization, the RUN bit of the status must be checked to be ensure that the RTC is frozen), then update TC values, and re-start the RTC by resetting STOP_RTC bit.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

19.3.5.15 Status Register (STATUS_REG)

The RTC STATUS_REG contains bits that signal the status of interrupts, events to the processor. Status for the alarm interrupt and timer events are notified by the register.

Figure 19-71. Status Register (STATUS_REG)

31							16
Reserved							
R-0							

15	7	6	5	4	3	2	1	0
Reserved		ALARM	1D_EVENT	1H_EVENT	1M_EVENT	1S_EVENT	RUN	BUSY
R-0		R/W-0	R-0	R-0	R-0	R-0	R-0	R-0

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 19-76. Status Register (STATUS_REG) Field Descriptions

Bit	Field	Value	Description
31-7	Reserved	0	Reserved
6	ALARM	0-1	Indicates that an alarm interrupt has been generated
5	1D_EVENT	0-1	One day has occurred
4	1H_EVENT	0-1	One hour has occurred
3	1M_EVENT	0-1	One minute has occurred
2	1S_EVENT	0-1	One second has occurred
1	RUN		RTC is frozen or is running.
		0	RTC is frozen
		1	RTC is running
0	BUSY		Status of RTC module.
		0	Updating event in more than 15 µs
		1	Updating event

NOTE:

- The alarm interrupt keeps its low level until the ARM writes 1 in the ALARM bit of the RTC_STATUS_REG register.
- ALARM: This bit will indicate the status of the alarm interrupt. Writing a 1 to the bit clears the interrupt.
- 1D_EVENT1: This bit will indicate if a day event has occurred. An interrupt will be generated to the processor based on the masking of the interrupt controller.
- 1H_EVENT1: This bit will indicate if an hour event has occurred. An interrupt will be generated to the processor based on the masking of the interrupt controller.
- 1M_EVENT1: This bit will indicate if a minute event has occurred. An interrupt will be generated to the processor based on the masking of the interrupt controller.
- 1S_EVENT1: This bit will indicate if a second event has occurred. An interrupt will be generated to the processor based on the masking of the interrupt controller.
- RUN: This bit will indicate if RTC is frozen or it is running. The RUN bit shows the real state of the RTC. Indeed, because the STOP_RTC signal is resynchronized on 32-kHz clock the action of this bit is delayed.
- BUSY: This bit will give the status of RTC module. The Time and alarm registers can be modified only when this bit is 0.
- The timer interrupt is a negative edge sensitive low-level pulse (1 OCP cycle duration).

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

19.3.5.16 Interrupt Register (INTERRUPTS_REG)

The INTERRUPTS_REG is used to enable or disable RTC from generating interrupts. The timer interrupt and alarm interrupt can be controlled using this register.

Figure 19-72. Interrupt Register (INTERRUPTS_REG)

31				16
Reserved				
R-0				

15	4	3	2	1	0
Reserved		IT_ALARM	IT_TIMER	EVERY	
R-0		R/W-0	R/W-0	R/W-0	

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 19-77. Interrupt Register (INTERRUPTS_REG) Field Descriptions

Bit	Field	Value	Description
31-4	Reserved	0	Reserved
3	IT_ALARM	0	Enable one interrupt when the alarm value is reached (TC ALARM registers) by the TC registers
2	IT_TIMER		Enable periodic interrupt.
		0	Interrupt disabled
		1	Interrupt enabled
1-0	EVERY	0-3h	Interrupt period.
		0	Every second
		1h	Every minute
		2h	Every hour
		3h	Every day

NOTE:

- The ARM must respect the BUSY period to prevent spurious interrupt. To set a period timer interrupt, the respective period value must be set in the EVERY field. For example, to set a periodic timer interrupt for every hour, the EVERY field has to be set to 2. Along with this the IT_TIMER bit also has to be set for the periodic interrupt to be generated.
- IT_ALARM bit has to be set to generate an alarm interrupt.

19.3.5.17 Compensation (LSB) Register (COMP_LSB_REG)

The COMP_LSB_REG is used to program the LSB value of the 32 kHz periods to be added to the 32 kHz counter every hour. This is used to compensate the oscillator drift. The COMP_LSB_REG works together with the compensation (MSB) register (COMP_MSB_REG). The AUTOCOMP bit in the control register (CTRL_REG) must be enabled for compensation to take place.

Figure 19-73. Compensation (LSB) Register (COMP_LSB_REG)

19.3.5.21 Kick Registers (KICK0R, KICK1R)

The kick registers (KICKnR) are used to enable and disable write protection on the RTC registers. Out of reset, the RTC registers are write-protected. To disable write protection, correct keys must be written to the KICKnR registers.

Kick0 Register (KICK0R)

The Kick0 register allows writing to unlock the kick0 data. To disable RTC register write protection, the value of 83E7 0B13h must be written to KICK0R, followed by the value of 95A4 F1E0h written to KICK1R. RTC register write protection is enabled when any value is written to KICK0R.

19.4 WATCHDOG

19.4.1 Introduction

The watchdog timer is an upward counter capable of generating a pulse on the reset pin and an interrupt to the device system modules following an overflow condition. The watchdog timer serves resets to the PRCM module and serves watchdog interrupts to the host ARM and DSP. The reset of the PRCM module causes warm reset of the device.

The watchdog timer can be accessed, loaded, and cleared by registers through the L4 interface. The watchdog timer have the 32-kHz clock for their timer clock input.

The watchdog timer connects to a single target agent port on the L4 interconnect. The default state of the watchdog timer is enabled and not running.

19.4.1.1 Features

The main features of the watchdog timer controllers are:

- L4 slave interface support:
  - 32-bit data bus width
  - 32-/16-bit access supported
  - 8-bit access not supported
  - 11-bit address bus width
  - Burst mode not supported
  - Write nonposted transaction mode only
- Free-running 32-bit upward counter
- Programmable divider clock source (2n where n = 0-7)
- On-the-fly read/write register (while counting)
- Subset programming model of the GP timer
- The watchdog timers are reset either on power-on or after a warm reset before they start counting.
- Reset or interrupt actions when a timer overflow condition occurs
- The watchdog timer generates a reset or an interrupt in its hardware integration.

19.4.1.2 Unsupported Featres

There are no unsupported WD Timer features in this device.

19.4.2 Integration

19.4.2.1 6.27.2. Public WD Timer Connectivity Attributes

The general connectivity for the WD Timer module in this device is shown in Table 19-87.

Table 19-87. Public WD Timer Module Connectivity Attributes

Attributes	Type
Power Domain	Wakeup Domain
Clock Domain	PD_WKUP_L4_WKUP_GCLK (OCP) PD_WKUP_WDT1_GCLK (Func)
Reset Signals	WKUP_DOM_RST_N
Idle/Wakeup Signals	Smart Idle / Slave Wakeup
Interrupt Requests	1 Interrupt to Sabertooth and WakeM3
DMA Requests	None
Physical Address	L4 Wakeup slave port

19.4.2.2 6.27.3. Public WD Timer Clock and Reset Management

The Watchdog Timer functional clock (pi_sys_clk input) is sourced from either the on-chip ~32678 Hz oscillator (CLK_RC32K) or the PER PLL generated 32.768 KHz clock (CLK_32KHZ) as selected using CLKSEL_WDT1_CLK[CLKSEL] in the PRCM.

Table 19-88. Public WD Timer Clock Signals

Clock Signal	Max Freq	Reference / Source	Comments
PI_OCP_CLK Interface clock	100 MHz	CORE_CLKOUTM4 / 2	pd_wkup_l4_wkup_gclk from PRCM
PI_SYS_CLK Functional clock	32768 Hz	CLK_RC32K or CLK_32KHZ (PER_CLKOUTM2 / 5859.375)	pd_wkup_wdt1_gclk from PRCM

19.4.3 Functional Description

19.4.3.1 Power Management

There are two clock domains in the watchdog timers:

- Functional clock domain: WDTi_FCLK is a 32 kHz watchdog timer functional clock. It is used to clock the watchdog timer internal logic.
- Interface clock domain: WDTi_ICLK is a 125 MHz watchdog timer interface clock. It is used to synchronize the watchdog timer L4 port to the L4 interconnect. All accesses from the interconnect are synchronous to WDTi_ICLK.

In this device, the clocks to the watchdog timers are always On. The clocks cannot be turned off, if the watchdog timers is not being used.

19.4.3.2 Interrupts

Table 19-89 list the event flags, and their masks, that cause module interrupts.

Table 19-89. Watchdog Timer Events

Event Flag	Event Mask	Mapping	Comments
WDT_WIRQSTAT[0] EVENT_OVF	WDT_WIRQENSET/WDT_WIRQENCLR[0] OVF_IT_ENA	WDTINT	Watchdog timer overflow
WDT_WIRQSTAT[1] EVENT_DLY	WDT_WIRQENSET/WDT_WIRQENCLR[1] DLY_IT_ENA	WDTINT	Watchdog delay value reached

19.4.3.3 General Watchdog Timer Operation

The watchdog timers are based on an upward 32-bit counter coupled with a prescaler. The counter overflow is signaled through two independent signals: a simple reset signal and an interrupt signal, both active low. Figure 19-82 is a functional block diagram of the watchdog timer.

The interrupt generation mechanism is controlled through the WDT_WIRQENSET/WDT_WIRQENCLR and WDT_WIRQSTAT registers.

The prescaler ratio can be set from 1 to 128 by accessing the WDT_WCLR[4:2] PTV bit field and the WDT_WCLR[5] PRE bit of the watchdog control register (WDT_WCLR).

The current timer value can be accessed on-the-fly by reading the watchdog timer counter register (WDT_WCRR), modified by accessing the watchdog timer load register (WDT_WLDR) (no on-the-fly update), or reloaded by following a specific reload sequence on the watchdog timer trigger register (WDT_WTGR). A start/stop sequence applied to the watchdog timer start/stop register (WDT_WSPR) can start and stop the watchdog timers.

Figure 19-82. 32-Bit Watchdog Timer Functional Block Diagram

Copyright © 2011, Texas Instruments Incorporated

19.4.3.4 Reset Context

The watchdog timers are enabled after reset. Table 19-90 lists the default reset values of the two watchdog timer load registers (the WDT_WLDR) and prescaler ratios (the WDT_WCLR[4:2] PTV bit field). To get these values, software must read the corresponding WDT_WCLR[4:2] PTV bit field and the 32-bit register to retrieve the static configuration of the module.

Table 19-90. Count and Prescaler Default Reset Values

Timer	WDT_WLDR Reset Value	PTV Reset Value
WDT	FFFF FFBEh	0

19.4.3.5 Overflow/Reset Generation

When the watchdog timer counter register (WDT_WCRR) overflows, an active-low reset pulse is generated to the PRCM module. This RESET pulse causes the PRCM module to generate global WARM reset of the device. It is also driven out of the device through the WD_OUT pin. This pulse is one prescaled timer clock cycle wide and occurs at the same time as the timer counter overflow.

After reset generation, the counter is automatically reloaded with the value stored in the watchdog load register (WDT_WLDR) and the prescaler is reset (the prescaler ratio remains unchanged). When the reset pulse output is generated, the timer counter begins incrementing again.

Figure 19-83 shows a general functional view of the watchdog timers.

Figure 19-83. Watchdog Timers General Functional View

19.4.3.6 Prescaler Value/Timer Reset Frequency

Each watchdog timer is composed of a prescaler stage and a timer counter.

The timer rate is defined by the following values:

- Value of the prescaler fields (the WDT_WCLR[5] PRE bit and the WDT_WCLR[4:2] PTV bit field)
- Value loaded into the timer load register (WDT_WLDR)

The prescaler stage is clocked with the timer clock and acts as a clock divider for the timer counter stage. The ratio is managed by accessing the ratio definition field (the WDT_WCLR[4:2] PTV bit field) and is enabled with the WDT_WCLR[5] PRE bit.

Table 19-91 lists the prescaler clock ratio values.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Table 19-91. Prescaler Clock Ratio Values

WDT_WCLR[5] PRE	WDT_WCLR[4:2] PTV	Clock Divider (PS)
0	X	1
1	0	1
1	1	2
1	2	4
1	3	8
1	4	16
1	5	32
1	6	64
1	7	128

Thus the watchdog timer overflow rate is expressed as:

OVF_Rate = (FFFF FFFFh – WDT_WLDR + 1) × (wd-functional clock period) × PS

where wd-functional clock period = 1/(wd-functional clock frequency) and PS = $2^{(PTV)}$

CAUTION

Internal resynchronization causes some latency in any software write to WDT_WSPR before WDT_WSPR is updated with the programmed value:

1.5 × functional clock cycles ≤ write_WDT_WSPR_latency ≤ 2.5 × functional clock cycles

Remember to consider this latency whenever the watchdog timer must be started or stopped.

For example, for a timer clock input of 32 kHz with a prescaler ratio value of 1 (clock divided by 2) and WDT_WCLR[5] PRE = 1 (clock divider enabled), the reset period is as listed in Table 19-92.

Table 19-92. Reset Period Examples

WDT_WLDR Value	Reset Period
0000 0000h	74 h 56 min
FFFF 0000h	4 s
FFFF FFF0h	1 ms
FFFF FFFFh	62.5 us

CAUTION

- Ensure that the reloaded value allows the correct operation of the application. When a watchdog timer is enabled, software must periodically trigger a reload before the counter overflows. Hence, the value of the WDT_WLDR[31:0] bit field must be chosen according to the ongoing activity preceding the watchdog reload.
- Due to design reasons, WDT_WLDR[31:0] = FFFF FFFFh is a special case, although such a value of WDT_WLDR is meaningless. When WDT_WLDR is programmed with the overflow value, a triggering event generates a reset/interrupt one functional clock cycle later, even if the watchdog timer is stopped.

Copyright © 2011, Texas Instruments Incorporated

Table 19-93 lists the default reset periods for the watchdog timers.

Table 19-93. Default Watchdog Timer Reset Periods

Watchdog Timers	Clock Source	Default Reset Period
WDT	32 kHz	2 s

19.4.3.7 Triggering a Timer Reload

To reload the timer counter and reset the prescaler before reaching overflow, a reload command is executed by accessing the watchdog timer trigger register (WDT_WTGR) using a specific reload sequence.

The specific reload sequence is performed whenever the written value on the WDT_WTGR register differs from its previous value. In this case, reload is executed in the same way as an overflow autoreload, but without the generation of a reset pulse.

The timer counter is loaded with the value of the watchdog timer load register (the WDT_WLDR[31:0] TIMER_LOAD bit field), and the prescaler is reset.

19.4.3.8 Start/Stop Sequence for Watchdog Timers (Using the WDT_WSPR Register)

To start and stop a watchdog timer, access must be made through the start/stop register (WDT_WSPR) using a specific sequence.

To disable the timer, follow this sequence:

1. Write XXXX AAAAh in WDT_WSPR.
2. Write XXXX 5555h in WDT_WSPR.

To enable the timer, follow this sequence:

1. Write XXXX BBBBh in WDT_WSPR.
2. Write XXXX 4444h in WDT_WSPR.

All other write sequences on the WDT_WSPR register have no effect on the start/stop feature of the module.

19.4.3.9 Modifying Timer Count/Load Values and Prescaler Setting

To modify the timer counter value (the WDT_WCRR register), prescaler ratio (the WDT_WCLR[4:2] PTV bit field), delay configuration value (the WDT_WDLY[31:0] DLY_VALUE bit field), or the load value (the WDT_WLDR[31:0] TIMER_LOAD bit field), the watchdog timer must be disabled by using the start/stop sequence (the WDT_WSPR register).

After a write access, the load register value and prescaler ratio registers are updated immediately, but new values are considered only after the next consecutive counter overflow or after a new trigger command (the WDT_WTGR register).

19.4.3.10 Watchdog Counter Register Access Restriction (WDT_WCRR Register)

A 32-bit shadow register is implemented to read a coherent value of the WDT_WCRR register because the WDT_WCRR register is directly related to the timer counter value and is updated on the timer clock (WDT_FCLK). The shadow register is updated by a 16-bit LSB read command.

NOTE: Although the L4 clock (WDT_ICLK) is completely asynchronous with the timer clock (WDT_FCLK), some synchronization is performed to ensure that the value of the WDT_WCRR register is not read while it is being incremented.

When 32-bit read access is performed, the shadow register is not updated. Read access is performed directly from the accessed register.

Copyright © 2011, Texas Instruments Incorporated

DRAFT ONLY

To ensure that a coherent value is read inside WDT_WCRR, the first read access is to the lower 16 bits (offset = 8h), followed by read access to the upper 16 bits (offset = Ah).

19.4.3.11 Watchdog Timer Interrupt Generation

When an interrupt source occurs, the interrupt status bit (the WDT_WIRQSTAT[0] EVENT_OVF or WDT_WIRQSTAT[1] EVENT_DLY bit) is set to 1. The output interrupt line (WDTi_IRQ) is asserted (active low) when status (the EVENT_xxx bit) and enable (the xxx_IT_ENA bit) flags are set to 1; the order is not relevant. Writing 1 to the enable bit (the status is already set at 1) also triggers the interrupt in the normal order (enable first, status next). The pending interrupt event is cleared when the set status bit is overwritten by a value of 1 by a write command in the WDT_WIRQSTAT register. Reading the WDT_WIRQSTAT register and writing the value back allows a fast interrupt acknowledge process.

The watchdog timer issues an overflow interrupt if this interrupt is enabled in the watchdog interrupt enable register (WDT_WIRQENSET[0] OVF_IT_ENA = 1). When the overflow occurs, the interrupt status bit (the WDT_WIRQSTAT[0] EVENT_OVF bit) is set to 1. The output interrupt line (WDT_IRQ) is asserted (active low) when status (EVENT_OVF) and enable (OVF_IT_ENA) flags are set to 1; the order is not relevant. This interrupt can be disabled by setting the WDT_WIRQENCLR[0] OVF_IT_ENA bit to 1.

The watchdog can issue the delay interrupt if this interrupt is enabled in the interrupt enable register (WDT_WIRQENSET[1] DLY_IT_ENA = 1). When the counter is running and the counter value matches the value stored in the delay configuration register (WDT_WDLY), the corresponding interrupt status bit is set in the watchdog status register (WDT_WIRQSTAT) and the output interrupt line is asserted (active low) when the flag (EVENT_DLY) and enable (DLY_IT_ENA) bits are 1 in the WDT_WIRQSTAT and WDT_WIRQENSET registers, respectively; the order (normally enable, then flag), is not relevant. This interrupt can be disabled by setting the WDT_WIRQENCLR[1] DLY_IT_ENA bit to 1.

NOTE: Writing 0 to the WDT_WIRQSTAT[0] EVENT_OVF bit or the WDT_WIRQSTAT[1] EVENT_DLY bit has no effect.

The two clock domains are resynchronized because the interrupt event is generated on the functional clock domain (WDTi_FCLK) during the updating of the interrupt status register (WDT_WIRQSTAT).

The WDT_WDLY register is used to specify the value of the delay configuration register. The delay time to interrupt is the difference between the reload value stored in the counter load register (WDT_WLDR) and the programmed value in this register (WDT_WDLY).

Use the following formula to estimate the delay time:

Delay time period = (WDT_WDLY – WDT_WLDR + 1) × Timer clock period × Clock divider

Where:

- Timer clock period = 1/(Timer clock frequency)
- Clock divider = 2PTV

If the counter value (WDT_WCRR) reaches the programmed value (WDT_WDLY), the status bit (EVENT_DLY) gets set in the interrupt status register (WDT_WIRQSTAT), and an interrupt occurs if the corresponding enable bit is set in the interrupt enable register (WDT_WIRQENSET).

CAUTION

If the reload event occurs (after a triggering sequence or after a reset sequence) before reaching the programmed value (WDT_WDLY[31:0] WDLY_VALUE), no interrupt is generated.

Also, no interrupt is generated if the value programmed in the delay configuration register (WDT_WDLY) is less than the value stored in the counter load register (WDT_WLDR).

Copyright © 2011, Texas Instruments Incorporated

19.4.3.12 Watchdog Timers Under Emulation

During emulation mode, the watchdog timer can/cannot continue running, according to the value of the WDT_WDSC[5] EMUFREE bit of the system configuration register (WDT_WDSC).

- When EMUFREE is 1, watchdog timer execution is not stopped and a reset pulse is still generated when overflow is reached.
- When EMUFREE is 0, the counters (prescaler/timer) are frozen and incrementation restarts after exiting from emulation mode.

19.4.3.13 Accessing Watchdog Timer Registers

Posted/nonposted selection applies only to functional registers that require synchronization on/from the timer functional clock domain (WDTi_FCLK). For write/read operation, the following registers are affected:

- WDT_WCLR
- WDT_WCRR
- WDT_WLDR
- WDT_WTGR
- WDT_WDLY
- WDT_WSPR

The timer interface clock domain synchronous registers are not affected by the posted/nonposted selection; the write/read operation is effective and acknowledged (command accepted) after one WDT_ICLK cycle from the command assertion. The timer interface clock domain synchronous registers are:

- WDT_WIDR
- WDT_WDSC
- WDT_WDST
- WDT_WIRQSTATRAW
- WDT_WIRQSTAT
- WDT_WIRQENSET
- WDT_WIRQENCLR
- WDT_WWPS

NOTE: Accesses to WDT2 and WDT3 are posted.

19.4.3.14 Low-Level Programming Model

This section covers the low-level hardware programming sequences for configuration and use of the module.

19.4.3.14.1 Global Initialization

19.4.3.14.1.1 Surrounding Modules Global Initialization

This section identifies the requirements for initializing the surrounding modules when the watchdog timer is to be used for the first time after a device reset. This initialization of surrounding modules is based on the integration and environment of the watchdog timer (see Table 19-94).

Table 19-94. Global Initialization of Surrounding Modules

Surrounding Modules	Comments
PRCM	The module interface and functional clocks must be enabled.
Control module	Module-specific pad multiplexing must be set in the control module.
MPU INTC	The MPU INTC configuration must be performed to enable the interrupts from the watchdog timer.

19.4.3.14.1.2 Main Sequence – Watchdog Timer Module Global Initialization

Table 19-95 lists the steps for initializing the watchdog timer module when the module is to be used for the first time.

Table 19-95. Watchdog Timer Module Global Initialization

Step	Register/Bit Field/Programming Model	Value
Execute software reset.	WDT_WDSC[1] SOFTRESET	1
Wait until reset release?	WDT_WDSC[1] SOFTRESET	0
Enable delay interrupt.	WDT_WIRQENSET[1] ENABLE_DLY	1
Enable overflow interrupt.	WDT_WIRQENSET[0] ENABLE_OVF	1

19.4.3.14.2 Operational Mode Configuration

19.4.3.14.2.1 Main Sequence – Watchdog Timer Basic Configuration

Table 19-96 lists the steps for the basic configuration of the watchdog timer.

Table 19-96. Watchdog Timer Basic Configuration

Step	Register/Bit Field/Programming Model	Value
Disable the watchdog timer.	See Section 19.4.3.14.2.2.

19.4.5 Watchdog Timer Registers

The watchdog timer registers are listed in Table 19-99.

CAUTION

The watchdog timers registers are limited to 32-bit and 16-bit data accesses; 8-bit access is not allowed and can corrupt register content.

NOTE:

- The WDT_WISR and WDT_WIRQSTATRAW registers have the same functionality. The WDT_WISR register is used for software backward compatibility.
- The WDT_WIER and WDT_WIRQENSET/WDT_WIRQENCLR registers have the same functionality. The WDT_WIER register is used for software backward compatibility.
- The WDT_WIRQSTATRAW and WDT_WIRQSTAT registers give the same information when read. The WDT_WIRQSTATRAW register is used for debug.

20.1 Introduction

The multi-master I2C peripheral provides an interface between a CPU and any I2C-bus-compatible device that connects via the I2C serial bus. External components attached to the I2C bus can serially transmit/receive up to 8-bit data to/from the CPU device through the two-wire I2C interface.

The I2C bus is a multi-master bus. The I2C controller does support the multi-master mode that allows more than one device capable of controlling the bus to be connected to it. Each I2C device is recognized by a unique address and can operate as either transmitter or receiver, according to the function of the device. In addition to being a transmitter or receiver, a device connected to the I2C bus can also be considered as master or slave when performing data transfers. Note that a master device is the device which initiates a data transfer on the bus and generates the clock signals to permit that transfer. During this transfer, any device addressed by this master is considered a slave.

20.1.1 I2C Features

The general features of the I2C controller are:

- Compliant with Philips I2C specification version 2.1
- Supports OmniVision Serial Camera Control Bus Protocol (SCCB)
- Supports standard mode (up to 100K bits/s), fast mode (up to 400K bits/s) and high speed mode (up to 3.4Mb/s).
- Multimaster transmitter/slave receiver mode
- Multimaster receiver/slave transmitter mode
- Combined master transmit/receive and receive/transmit modes
- 7-bit and 10-bit device addressing modes
- Built-in FIFO for buffered read or write
  - I2C0: 32 bytes
  - I2C1: 32 bytes
- Programmable clock generation
- Two DMA channels, one interrupt line

20.1.2 Unsupported I2C Features

The I2C module features not supported in this device are shown in Table 20-1.

Table 20-1. Unsupported I2C Features

Feature	Reason
SCCB Protocol	SCCB signal not pinned out
High Speed (3.4 MBPS) operation	Not required

20.2 Integration

This device includes three instantiations of the I2C module. This peripheral implements the multi-master I2C bus which allows serial transfer of 8-bit data to/from other I2C master/slave devices through a two-wire interface. There are three I2C modules instantiations called I2C0, I2C1, and I2C2. The I2C0 module is located in the Wake-up power domain. Figure 20-1 and Figure 20-2 show examples of a system with multiple I2C-compatible devices.

Figure 20-1. I2C0 Integration and Bus Application

Figure 20-2. I2C(1–2) Integration and Bus Application

20.2.1 I2C Connectivity Attributes

The general connectivity attributes for the I2C module are shown in Table 20-2 and Table 20-3.

Table 20-2. I2C0 Connectivity Attributes

Attributes	Type
Power Domain	Wakeup Domain
Clock Domain	PD_WKUP_L4_WKUP_GCLK (OCP) PD_WKUP_I2C0_GFCLK (Func)
Reset Signals	WKUP_DOM_RST_N
Idle/Wakeup Signals	Smart Idle / Wakeup
Interrupt Requests	1 interrupt to MPU Subsystem, PRUSS and WakeM3
DMA Requests	2 DMA requests to EDMA
Physical Address	L4 Wakeup slave port

Table 20-3. I2C(1–2) Connectivity Attributes

Attributes	Type

Clock Domain	PD_PER_L4LS_GCLK (OCP) PD_PER_I2C_FCLK (Func)
Reset Signals	PER_DOM_RST_N
Idle/Wakeup Signals	Smart Idle
Interrupt Requests	1 interrupt to MPU Subsystem
DMA Requests	2 DMA requests to EDMA
Physical Address	L4 Peripheral slave port

20.2.2 I2C Clock and Reset Management

The I2C controllers have separate bus interface and functional clocks. During power-down mode, the I2C*x*_SCL and I2C*x*_SDA are configured as inputs.

Table 20-4. I2C Clock Signals

Clock Signal	Max Freq	Reference / Source	Comments
I2C0 Clock Signals			
PIOCPCLK Interface clock	100 MHz	CORE_CLKOUTM4 / 2	pd_wkup_l4_wkup_gclk From PRCM

20.3 Functional Description

20.3.1 Functional Block Diagram

Figure 20-3 shows an example of a system with multiple I2C compatible devices in which the I2C serial ports are all connected together for a two-way transfer from one device to other devices.

Figure 20-3. I2C Functional Block Diagram

The I2C peripheral consists of the following primary blocks:

- A serial interface: one data pin (I2C_SDA) and one clock pin (I2C_SCL).
- Data registers to temporarily hold receive data and transmit data traveling between the I2C_SDA pin and the CPU or the DMA controller.
- Control and status registers
- A peripheral data bus interface to enable the CPU and the DMA controller to access the I2C peripheral registers.
- A clock synchronizer to synchronize the I2C input clock (from the processor clock generator) and the clock on the I2C_SCL pin, and to synchronize data transfers with masters of different clock speeds.
- A prescaler to divide down the input clock that is driven to the I2C peripheral
- A noise filter on each of the two pins, I2C_SDA and I2C_SCL
- An arbitrator to handle arbitration between the I2C peripheral (when it is a master) and another master
- Interrupt generation logic, so that an interrupt can be sent to the CPU
- DMA event generation logic to send an interrupt to the CPU upon reception and data transmission of data.

20.3.2 I2C Master/Slave Contoller Signals

Data is communicated to devices interfacing with the I2C via the serial data line (SDA) and the serial clock line (SCL). These two wires can carry information between a device and others connected to the I2C bus. Both SDA and SCL are bi-directional pins. They must be connected to a positive supply voltage via a pull-up resistor. When the bus is free, both pins are high. The driver of these two pins has an open drain to perform the required wired-AND function.

An example of multiple I2C modules that are connected for a two-way transfer from one device to other devices is shown in Figure 20-4.

Figure 20-4. Multiple I2C Modules Connected

Table 20-6. Signal Pads

	I2C Mode	
Name	**Default Operating Mode**	**Description**
I2C_SCL	In/ Out	I2C serial CLK line Open-drain output buffer. Requires external pull-up resistor (Rp).
I2C_SDA	In/ Out	I2C serial data line Open-drain output buffer. Requires external pull-up resistor (Rp).

20.3.3 I2C Reset

The I2C module can be reset in the following three ways:

- A system reset (PIRSTNA = 0). A device reset causes the system reset. All registers are reset to power up reset values.
- A software reset by setting the SRST bit in the I2C_SYSC register. This bit has exactly the same action on the module logic as the system bus reset. All registers are reset to power up reset values.
- The I2C_EN bit in the I2C_CON register can be used to hold the I2C module in reset. When the system bus reset is removed (PIRSTNA = 1), I2C_EN = 0 keeps the functional part of I2C module in reset state and all configuration registers can be accessed. I2C_EN = 0 does not reset the registers to power up reset values.

Table 20-7. Reset State of I2C Signals

			I2C Reset
Pin	**I/O/Z** [(1)]	**System Reset**	**(I2C_EN = 0)**
SDA	I/O/Z	High impedance	High impedance
SCL	I/O/Z	High impedance	High impedance

(1) I = Input, O = Outpu, Z = High impedance

20.3.4 Data Validity

The data on the SDA line must be stable during the high period of the clock. The high and low states of the data line can only change when the clock signal on the SCL line is LOW.

20.3.5 START & STOP Conditions

The I2C module generates START and STOP conditions when it is configured as a master.

- START condition is a high-to-low transition on the SDA line while SCL is high.
- STOP condition is a low-to-high transition on the SDA line while SCL is high.
- The bus is considered to be busy after the START condition (BB = 1) and free after the STOP condition (BB = 0).

Figure 20-6. Start and Stop Condition Events

20.3.6 I2C Operation

20.3.6.1 Serial Data Formats

The I2C controller operates in 8-bit word data format (byte write access supported for the last access). Each byte put on the SDA line is 8 bits long. The number of bytes that can be transmitted or received is restricted by the value programmed in the DCOUNT register. The data is transferred with the most significant bit (MSB) first. Each byte is followed by an acknowledge bit from the I2C module if it is in receiver mode.

Figure 20-7. I2C Data Transfer

The I2C module supports two data formats, as shown in Figure 20-8:

- 7-bit/10-bit addressing format
- 7-bit/10-bit addressing format with repeated start condition

The first byte after a start condition (S) always consists of 8 bits. In the acknowledge mode, an extra bit dedicated for acknowledgment is inserted after each byte. In the addressing formats with 7-bit addresses, the first byte is composed of 7 MSB slave address bits and 1 LSB R/nW bit. In the addressing formats with 10-bit addresses, the first byte is composed of 7 MSB slave address bits, such as 11110XX, where XX is the two MSB of the 10-bit addresses, and 1 LSB R/nW bit, which is 0 in this case.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

The least significant R/nW of the address byte indicates the direction of transmission of the following data bytes. If R/nW is 0, the master writes data into the selected slave; if it is 1, the master reads data out of the slave.

Figure 20-8. I2C Data Transfer Formats

20.3.6.2 Master Transmitter

In this mode, data assembled in one of the previously described data formats is shifted out on the serial data line SDA in synch with the self-generated clock pulses on the serial clock line SCL. The clock pulses are inhibited and SCL held low when the intervention of the processor is required (XUDF) after a byte has been transmitted.

20.3.6.3 Master Receiver

This mode can only be entered from the master transmitter mode. With either of the address formats (Figure 6 (a), (b), and (c)), the master receiver is entered after the slave address byte and bit R/W_ has been transmitted, if R/W_ is high. Serial data bits received on bus line SDA are shifted in synch with the self-generated clock pulses on SCL. The clock pulses are inhibited and SCL held low when the intervention of the processor is required (ROVR) after a byte has been transmitted. At the end of a transfer, it generates the stop condition.

20.3.6.4 Slave Transmitter

This mode can only be entered from the slave receiver mode. With either of the address formats (Figure 6 (a), (b), and (c)), the slave transmitter is entered if the slave address byte is the same as its own address and bit R/W_ has been transmitted, if R/W_ is high. The slave transmitter shifts the serial data out on the data line SDA in synch with the clock pulses that are generated by the master device. It does not generate the clock but it can hold clock line SCL low while intervention of the CPU is required (XUDF).

20.3.6.5 Slave Receiver

In this mode, serial data bits received on the bus line SDA are shifted-in in synch with the clock pulses on SCL that are generated by the master device. It does not generate the clock but it can hold clock line SCL low while intervention of the CPU is required (ROVR) following the reception of a byte.

20.3.7 Arbitration

If two or more master transmitters start a transmission on the same bus almost simultaneously, an arbitration procedure is invoked. The arbitration procedure uses the data presented on the serial bus by the competing transmitters. When a transmitter senses that a high signal it has presented on the bus has been overruled by a low signal, it switches to the slave receiver mode, sets the arbitration lost (AL) flag, and generates the arbitration lost interrupt. Figure 20-9 shows the arbitration procedure between two devices. The arbitration procedure gives priority to the device that transmits the serial data stream with the lowest binary value. Should two or more devices send identical first bytes, arbitration continues on the subsequent bytes.

Figure 20-9. Arbitration Procedure Between Two Master Transmitters

20.3.8 I2C Clock Generation and I2C Clock Synchronization

Under normal conditions, only one master device generates the clock signal, SCL. During the arbitration procedure, however, there are two or more master devices and the clock must be synchronized so that the data output can be compared. The wired-AND property of the clock line means that a device that first generates a low period of the clock line overrules the other devices. At this high/low transition, the clock generators of the other devices are forced to start generation of their own low period. The clock line is then held low by the device with the longest low period, while the other devices that finish their low periods must wait for the clock line to be released before starting their high periods. A synchronized signal on the clock line is thus obtained, where the slowest device determines the length of the low period and the fastest the length of the high period.

If a device pulls down the clock line for a longer time, the result is that all clock generators must enter the WAIT-state. In this way a slave can slow down a fast master and the slow device can create enough time to store a received byte or to prepare a byte to be transmitted. Figure 20-10 illustrates the clock synchronization.

Figure 20-10. Synchronization of Two I2C Clock Generators

20.3.9 Prescaler (SCLK/ICLK)

The I2C module is operated with a functional clock (SCLK) frequency that can be in a range of 12-100 MHz, according to I2C mode that must be used (an internal ~24 MHz clock (ICLK) is recommended in case of F/S operation mode e). Note that the frequency of the functional clock influences directly the I2C bus performance and timings.

The internal clock used for I2C logic - ICLK - is generated via the I2C prescaler block. The prescaler consists of a 4-bit register - I2C _PSC, and is used to divide the system clock (SCLK) to obtain the internal required clock for the I2C module.

20.3.10 Noise Filter

The noise filter is used to suppress any noise that is 50 ns or less, in the case of F/S mode of operation. It is designed to suppress noise with one ICLK. The noise filter is always one ICLK cycle, regardless of the bus speed. For FS mode (prescaler = 4, ICLK = 24 MHz), the maximum width of the suppressed spikes is 41.6 ns. To ensure a correct filtering, the prescaler must be programmed accordingly.

20.3.11 I2C Interrupts

The I2C module generates 12 types of interrupt: addressed as slave, bus free (stop condition detected), access error, start condition, arbitration-lost, noacknowledge, general call, registers-ready-for-access, receive and transmit data, receive and transmit draining. These 12 interrupts are accompanied with 12 interrupt masks and flags defined in the I2C_IRQENABLE_SET and respectively I2C_IRQSTATUS_RAW registers. Note that all these 12 interrupt events are sharing the same hardware interrupt line.

- Addressed As Slave interrupt (AAS) is generated to inform the Local Host that an external master addressed the module as a slave. When this interrupt occurs, the CPU can check the I2C_ACTOA status register to check which of the 4 own addresses was used by the external master to access the module.
- Bus Free interrupt (BF) is generated to inform the Local Host that the I2C bus became free (when a Stop Condition is detected on the bus) and the module can initiate his own I2C transaction.
- Start Condition interrupt (STC) is generated after the module being in idle mode have detected (synchronously or asynchronously) a possible Start Condition on the bus (signalized with WakeUp).
- Access Error interrupt (AERR) is generated if a Data read access is performed while RX FIFO is empty or a Data write access is performed while TX FIFO is full.
- Arbitration lost interrupt (AL) is generated when the I2C arbitration procedure is lost.
- No-acknowledge interrupt (NACK) is generated when the master I2C does not receive acknowledge from the receiver.
- General call interrupt (GC) is generated when the device detects the address of all zeros (8 bits).
- Registers-ready-for-access interrupt (ARDY) is generated by the I2C when the previously programmed address, data, and command have been performed and the status bits have been updated. This interrupt is used to let the CPU know that the I2C registers are ready for access.
- Receive interrupt/status (RRDY) is generated when there is received data ready to be read by the CPU from the I2C_DATA register (see the FIFO Management subsection for a complete description of required conditions for interrupt generation). The CPU can alternatively poll this bit to read the received data from the I2C_DATA register.
- Transmit interrupt/status (XRDY) is generated when the CPU needs to put more data in the I2C_DATA register after the transmitted data has been shifted out on the SDA pin (see the FIFO Management subsection for a complete description of required conditions for interrupt generation). The CPU can alternatively poll this bit to write the next transmitted data into the I2C_DATA register.
- Receive draining interrupt (RDR) is generated when the transfer length is not a multiple of threshold value, to inform the CPU that it can read the amount of data left to be transferred and to enable the draining mechanism. (see the Draining Feature subsection for additional details).
- Transmit draining interrupt (XDR) is generated when the transfer length is not a multiple of threshold value, to inform the CPU that it can read the amount of data left to be written and to enable the draining mechanism. (see the Draining Feature subsection for additional details).

Copyright © 2011, Texas Instruments Incorporated

When the interrupt signal is activated, the Local Host must read the I2C_IRQSTATUS_RAW register to define the type of the interrupt, process the request, and then write into these registers the correct value to clear the interrupt flag.

20.3.12 DMA Events

The I2C module can generate two DMA requests events, read (I2C_DMA_RX) and write (I2C_DMA_TX) that can be used by the DMA controller to synchronously read received data from the I2C_DATA or write transmitted data to the I2C_DATA register. The DMA read and write requests are generated in a similar manner as RRDY and XRDY, respectively.

The I2C DMA request signals (I2C_DMA_TX and I2C_DMA_RX) are activated according to the FIFO Management subsection.

20.3.13 Interrupt and DMA Events

I2C has two DMA channels (Tx and Rx). For event numbers, see the data manual.

I2C has one interrupt line for all the interrupt requests. For the interrupt number, see the data manual.

20.3.14 FIFO Management

The I2C module implements two internal 32-bytes FIFOs with dual clock for RX and TX modes. The depth of the FIFOs can be configured at integration via a generic parameter which will also be reflected in I2C_IRQSTATUS_RAW.FIFODEPTH register.

20.3.14.1 FIFO Interrupt Mode Operation

In FIFO interrupt mode (relevant interrupts enabled via I2C_IRQENABLE_SET register), the processor is informed of the status of the receiver and transmitter by an interrupt signal. These interrupts are raised when receive/transmit FIFO threshold (defined by I2C_BUF.TXTRSH or I2C_BUF.RXTRSH) are reached; the interrupt signals instruct the Local Host to transfer data to the destination (from the I2C module in receive mode and/or from any source to the I2C FIFO in transmit mode).

Figure 20-11 and Figure 20-12, respectively, illustrate receive and transmit operations from FIFO management point of view.

Figure 20-11. Receive FIFO Interrupt Request Generation

Note that in Figure 20-11, the RRDY Condition illustrates that the condition for generating a RRDY interrupt is achieved. The interrupt request is generated when this signal is active, and it can be cleared only by the CPU by writing a 1 in the corresponding interrupt flag. If the condition is still present after clearing the previous interrupt, another interrupt request will be generated.

Copyright © 2011, Texas Instruments Incorporated

In receive mode, RRDY interrupt is not generated until the FIFO reaches its receive threshold. Once low, the interrupt can only be de-asserted when the Local Host has handled enough bytes to make the FIFO level below threshold. For each interrupt, the Local Host can be configured to read an amount of bytes equal with the value of the RX FIFO threshold + 1.

Figure 20-12. Transmit FIFO Interrupt Request Generation

Note that in the figure above, the XRDY Condition illustrates that the condition for generating a XRDY interrupt is achieved. The interrupt request is generated when this condition is achieved (when TX FIFO is empty, or the TX FIFO threshold is not reached and there are still data bytes to be transferred in the TX FIFO), and it can be cleared only by the CPU by writing a 1 in the corresponding interrupt flag after transmitting the configured number of bytes. If the condition is still present after clearing the previous interrupt, another interrupt request will be generated.

Note that in interrupt mode, the module offers two options for the CPU application to handle the interrupts:

- When detecting an interrupt request (XRDY or RRDY type), the CPU can write/read one data byte to/from the FIFO and then clear the interrupt. The module will not reassert the interrupt until the interrupt condition is not met.
- When detecting an interrupt request (XRDY or RRDY type), the CPU can be programmed to write/read the amount of data bytes specified by the corresponding FIFO threshold (I2C_BUF.TXTRSH + 1 or I2C_BUF.RXTRSH + 1). In this case, the interrupt condition will be cleared and the next interrupt will be asserted again when the XRDY or RRDY condition will be again met.

If the second interrupt serving approach is used, an additional mechanism (draining feature) is implemented for the case when the transfer length is not a multiple of FIFO threshold (see the Draining Feature subsection).

In slave TX mode, the draining feature cannot be used, since the transfer length is not known at the configuration time, and the external master can end the transfer at any point by not acknowledging one data byte.

20.3.14.2 FIFO Polling Mode Operation

In FIFO polled mode (I2C_IRQENABLE_SET.XRDY_IE and I2C_IRQENABLE_SET.RRDY_IE disabled and DMA disabled), the status of the module (receiver or transmitter) can be checked by polling the XRDY and RRDY status registers (I2C_IRQSTATUS_RAW) (RDR and XDR can also be polled if draining feature must be used). The XRDY and RRDY flags are accurately reflecting the interrupt conditions mentioned in Interrupt Mode. This mode is an alternative to the FIFO interrupt mode of operation, where the status of the receiver and transmitter is automatically known by means of interrupts sent to the CPU.

Copyright © 2011, Texas Instruments Incorporated

20.3.14.3 FIFO DMA Mode Operation

In receive mode, a DMA request is generated as soon as the receive FIFO exceeds its threshold level defined in the threshold level register (I2C_BUF.RXTRSH +1). This request should be de-asserted when the number of bytes defined by the threshold level has been read by the DMA, by setting the I2C_DMARXENABLE_CLR.DMARX_ENABLE_CLEAR field.

Figure 20-13. Receive FIFO DMA Request Generation

In transmit mode, a DMA request is automatically asserted when the transmit FIFO is empty. This request should be de-asserted when the number of bytes defined by the number in the threshold register (I2C_BUF.TXTHRS+1) has been written in the FIFO by the DMA, by setting the I2C_DMATXENABLE_CLR. DMATX_ENABLE_CLEAR field. If an insufficient number of characters are written, then the DMA request will remain active. Figure 20-14 and Figure 20-15 illustrate DMA TX transfers with different values for TXTRSH.

Figure 20-14. Transmit FIFO DMA Request Generation (High Threshold)

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Figure 20-15. Transmit FIFO DMA Request Generation (Low Threshold)

Note that also in DMA mode it is possible to have a transfer whose length is not multiple of the configured FIFO threshold. In this case, the DMA draining feature is also used for transferring the additional bytes of the transfer (see the Draining Feature subsection for additional details).

According to the desired operation mode, the programmer must set the FIFO thresholds according to the following table (note that only the OCP side thresholds can be programmed; the I2C side thresholds are default equals to 1). Note that the thresholds must be set consistent with the DMA channel length.

In I2C Slave RX Mode, the Local Host can program the RX threshold with the desired value, and use the FIFO draining feature at the end of the I2C transfer to extract from the FIFO the remaining bytes if the threshold is not reached (see the Draining Feature subsection for additional details).

Note that in I2C Slave TX Mode, the TX FIFO threshold should be set to 1 (I2C_BUF.TXTRSH=0, default value), since the length of the transfer may not be known at configuration time. In this way, the interrupt (or accordingly, DMA) requests will be generated for each byte requested by the remote I2C master to be transferred over the I2C bus. This configuration will prevent the I2C core to request additional data from the CPU or from the DMA controller (using IRQ or DMA), data that will eventually not be extracted from the FIFO by the external master (which can use not acknowledge at any time to end the transfer). If the TX threshold is not set to 1, the module will generate an interrupt or assert a DMA only when the external master requests a byte and the FIFO is empty. However, in this case the TX FIFO will require to be cleared at the end of the transfer.

The I2C module offers the possibility to the user to clear the RX or TX FIFO. This is achieved through I2C_BUF.RXFIFO_CLR and I2C_BUF.TXFIFO_CLR registers, which act like software reset for the FIFOs. In DMA mode, these bits will also reset the DMA state machines.

The FIFO clearing feature can be used when the module is configured as a transmitter, the external receiver responds with a NACK in the middle of the transfer, and there is still data in TX FIFO waiting to be transferred.

On the Functional (I2C) domain, the thresholds can always be considered equal to 1. This means that the I2C Core can start transferring data on the I2C bus whenever it has data in the FIFOs (FIFO is not empty).

20.3.14.4 Draining Feature

The Draining Feature is implemented by the I2C core for handling the end of the transfers whose length is not a multiple of FIFO threshold value, and offers the possibility to transfer the remaining amount of bytes (since the threshold is not reached).

Note that this feature prevents the CPU or the DMA controller to attempt more FIFO accesses than necessary (for example, to generate at the end of a transfer a DMA RX request having in the FIFO less bytes than the configured DMA transfer length). Otherwise, an Access Error interrupt will be generated (see I2C_IRQSTATUS_RAW.AERR interrupt).

The Draining mechanism will generate an interrupt (I2C_IRQSTATUS_RAW.RDR or I2C_IRQSTATUS_RAW.XDR) at the end of the transfer informing the CPU that it needs to check the amount of data left to be transferred (I2C_BUFSTAT.TXSTAT or RXSTAT) and to enable the Draining Feature of the DMA controller if DMA mode is enabled (by re-configuring the DMA transfer length according to this value), or perform only the required number of data accesses, if DMA mode is disabled.

In receiving mode (master or slave), if the RX FIFO threshold is not reached but the transfer was ended on the I2C bus and there is still data left in the FIFO (less than the threshold), the receive draining interrupt (I2C_IRQSTATUS_RAW.RDR) will be asserted to inform the local host that it can read the amount of data in the FIFO (I2C_BUFSTAT.RXSTAT). The CPU will perform a number of data read accesses equal with RXSTAT value (if interrupt or polling mode) or re-configure the DMA controller with the required value in order to drain the FIFO.

In master transmit mode, if the TX FIFO threshold is not reached but the amount of data remained to be written in the FIFO is less than TXTRSH, the transmit draining interrupt (I2C_IRQSTATUS_RAW.XDR) will be asserted to inform the local host that it can read the amount of data remained to be written in the TX FIFO (I2C_BUFSTAT.TXSTAT). The CPU will need to write the required number of data bytes (specified by TXSTAT value) or re-configure the DMA controller with the required value in order to transfer the last bytes to the FIFO.

Note that in master mode, the CPU can alternatively skip the checking of TXSTAT and RXSTAT values since it can obtain internally this information (by computing DATACOUNT modulo TX/RXTHRSH).

The draining feature is default disabled, and it can be enabled using I2C_IRQENABLE_SET.XDR_IE or I2C_IRQENABLE_SET.RDR_IE registers (default disabled) only for the transfers with length not equal with the threshold value.

20.3.15 How to Program I2C

20.3.15.1 Module Configuration Before Enabling the Module

1. Program the prescaler to obtain an approximately 12-MHz I2C module clock (I2C_PSC = x; this value is to be calculated and is dependent on the System clock frequency).
2. Program the I2C clock to obtain 100 Kbps or 400 Kbps (SCLL = x and SCLH = x; these values are to be calculated and are dependent on the System clock frequency).
3. Configure its own address (I2C_OA = x) - only in case of I2C operating mode (F/S mode).
4. Take the I2C module out of reset (I2C_CON:I2C_EN = 1).

20.3.15.2 Initialization Procedure

1. Configure the I2C mode register (I2C_CON) bits.
2. Enable interrupt masks (I2C_IRQENABLE_SET), if using interrupt for transmit/receive data.
3. Enable the DMA (I2C_BUF and I2C_DMA/RX/TX/ENABLE_SET) and program the DMA controller) - only in case of I2C operating mode (F/S mode), if using DMA for transmit/receive data.

20.3.15.3 Configure Slave Address and DATA Counter Registers

In master mode, configure the slave address (I2C_SA = x) and the number of byte associated with the transfer (I2C_CNT = x).

Copyright © 2011, Texas Instruments Incorporated

20.3.15.4 Initiate a Transfer

Poll the bus busy (BB) bit in the I2C status register (I2C_IRQSTATUS_RAW). If it is cleared to 0 (bus not busy), configure START/STOP (I2C_CON: STT / I2C_CON: STP condition to initiate a transfer) - only in case of I2C operating mode (F/S mode).

20.3.15.5 Receive Data

Poll the receive data ready interrupt flag bit (RRDY) in the I2C status register (I2C_IRQSTATUS_RAW), use the RRDY interrupt (I2C_IRQENABLE_SET.RRDY_IE set) or use the DMA RX (I2C_BUF.RDMA_EN set together with I2C_DMARXENABLE_SET) to read the receive data in the data receive register (I2C_DATA). Use draining feature (I2C_IRQSTATUS_RAW.RDR enabled by I2C_IRQENABLE_SET.RDR_IE)) if the transfer length is not equal with FIFO threshold.

20.3.15.6 Transmit Data

Poll the transmit data ready interrupt flag bit (XRDY) in the I2C status register (I2C_IRQSTATUS_RAW), use the XRDY interrupt (I2C_IRQENABLE_SET.XRDY_IE set) or use the DMA TX (I2C_BUF.XDMA_EN set together with I2C_DMATXENABLE_SET) to write data into the data transmit register (I2C_DATA). Use draining feature (I2C_IRQSTATUS_RAW.XDR enabled by I2C_IRQENABLE_SET.XDR_IE)) if the transfer length is not equal with FIFO threshold.

Table 20-11. System Configuration Register (I2C_SYSC) Field Descriptions

Bit	Field	Value	Description
31-10	Reserved	0	Reserved
9-8	CLKACTIVITY		Clock Activity selection bits. Those bits (one bit for each clock signal present on the boundary of the module) are set to 1 to disable external clock gating mechanism in Idle Mode.
		0h	Both clocks can be cut off
		1h	Only OCP clock must be kept active; system clock can be cut off
		2h	Only system clock must be kept active; OCP clock can be cut off
		3h	Both clocks must be kept active
			Values after reset are low (for both 2 bits).
			Note: If the System (functional) Clock is cut-off, the module will assert a WakeUp event when it will asynchronously detect a Start Condition on the I2C Bus. Note that in this case the first transfer will not be taken into account by the module (NACK will be detected by the external master).
7-5	Reserved	0	Reads return 0h.
4-3	IDLEMODE		Idle Mode selection bits. These two bits are used to select one of the idle mode operation mechanisms.
		0h	Force Idle mode
		1h	No Idle mode
		2h	Smart Idle mode
		3h	smartidle_wakeup
			Value after reset is 00 (Force Idle).
2	ENAWAKEUP		Enable Wakeup control bit. When this bit is set to 1, the module enables its own wakeup mechanism.
		0	Wakeup mechanism is disabled
		1	Wakeup mechanism is enabled
			Value after reset is low.
1	SRST		SoftReset bit. When this bit is set to 1, entire module is reset as for the hardware reset. This bit is automatically cleared to 0 by the core and it is only reset by the hardware reset. During reads, it always returns 0.
		0	Normal mode
		1	The module is reset
			Value after reset is low.
0	AUTOIDLE		Autoidle bit. When this bit is set to 1, the module activates its own idle mode mechanism. By evaluating its internal state, the module can decide to gate part of his internal clock tree in order to improve the overall power consumption.
		0	Auto Idle mechanism is disabled
		1	Auto Idle mechanism is enabled
			Value after reset is high.

20.4.5 I2C Status Raw Register (I2C_IRQSTATUS_RAW)

This register provides core status information for interrupt handling, showing all active events (enabled and not enabled). The fields are read-write. Writing a 1 to a bit will set it to 1, that is, trigger the IRQ (mostly for debug). Writing a 0 will have no effect, that is, the register value will not be modified. Only enabled, active events will trigger an actual interrupt request on the IRQ output line.

Table 20-13. I2C Status Raw Register (I2C_IRQSTATUS_RAW) Field Descriptions

Bit	Field	Value	Description
31-15	Reserved	0	Write 0s for future compatibility. Read returns 0.
14	XDR		Transmit draining IRQ status. I2C Master Transmit mode only. This read/clear only bit is set to 1 when the module is configured as a master transmitter, the TX FIFO level is below the configured threshold (TXTRSH) and the amount of data still to be transferred is less than TXTRSH. When this bit is set to 1 by the core, CPU must read the I2C_BUFSTAT.TXSTAT register in order to check the amount of data that need to be written in the TX FIFO. Then, according to the mode set (DMA or interrupt), the CPU can enable the DMA draining feature of the DMA controller with the number of data bytes to be transferred (I2C_BUFSTAT.TXSTAT), or generate write data accesses according to this value (IRQ mode). The interrupt needs to be cleared after the DMA controller was reconfigured (if DMA mode enabled), or before generating data accesses to the FIFO (if IRQ mode enabled). If the corresponding interrupt was enabled, an interrupt is signaled to the local host. The CPU can also poll this bit. For more details about TDR generation, refer to the FIFO Management subsection. The CPU can only clear this bit by writing a 1 into this register. A write 0 has no effect.
		0	Transmit draining inactive
		1	Transmit draining enabled
			Value after reset is low.

Table 20-13. I2C Status Raw Register (I2C_IRQSTATUS_RAW) Field Descriptions (continued)

Bit	Field	Value	Description
13	RDR		Receive draining IRQ status. I2C Receive mode only. This read/clear only bit is set to 1 when the module is configured as a receiver, a stop condition was received on the bus and the RX FIFO level is below the configured threshold (RXTRSH). When this bit is set to 1 by the core, CPU must read the I2C_BUFSTAT.RXSTAT register in order to check the amount of data left to be transferred from the FIFO. Then, according to the mode set (DMA or interrupt), the CPU needs to enable the draining feature of the DMA controller with the number of data bytes to be transferred (I2C_BUFSTAT.RXSTAT), or generate read data accesses according to this value (IRQ mode). The interrupt needs to be cleared after the DMA controller was reconfigured (if DMA mode enabled), or before generating data accesses to the FIFO (if IRQ mode enabled). If the corresponding interrupt was enabled, an interrupt is signaled to the local host. The CPU can also poll this bit. For more details about RDR generation, refer to the FIFO Management subsection. The CPU can only clear this bit by writing a 1 into this register. A write 0 has no effect.
		0	Receive draining inactive
		1	Receive draining enabled
			Value after reset is low.
12	BB		This read-only bit indicates the state of the serial bus. In slave mode, on reception of a start condition, the device sets BB to 1. BB is cleared to 0 after reception of a stop condition. In master mode, the software controls BB. To start a transmission with a start condition, MST, TRX, and STT must be set to 1 in the I2C_CON register. To end a transmission with a stop condition, STP must be set to 1 in the I2C_CON register. When BB = 1 and STT = 1, a restart condition is generated.
		0	Bus is free
		1	Bus is occupied
			Value after reset is low.
11	ROVR		Receive overrun status. Writing into this bit has no effect. I2C receive mode only. This read-only bit indicates whether the receiver has experienced overrun. Overrun occurs when the shift register is full and the receive FIFO is full. An overrun condition does not result in a data loss; the peripheral is just holding the bus (low on SCL) and prevents other bytes from being received. ROVR is set to 1 when the I2C has recognized an overrun. ROVR is clear when reading I2C_DATA register, or when resetting the I2C (I2C_CON:I2C_EN = 0).
		0	Normal operation
		1	Receiver overrun
			Value after reset is low.
10	XUDF		Transmit underflow status. Writing into this bit has no effect. I2C transmit mode only. This read-only bit indicates whether the transmitter has experienced underflow. In master transmit mode, underflow occurs when the shift register is empty, the transmit FIFO is empty, and there are still some bytes to transmit (DCOUNT 0). In slave transmit mode, underflow occurs when the shift register is empty, the transmit FIFO is empty, and there are still some bytes to transmit (read request from external I2C master). XUDF is set to 1 when the I2C has recognized an underflow. The core holds the line till the underflow cause has disappeared. XUDF is clear when writing I2C_DATA register or resetting the I2C (I2C_CON:I2C_EN = 0).
		0	Normal operation
		1	Transmit underflow
			Value after reset is low.

Table 20-13. I2C Status Raw Register (I2C_IRQSTATUS_RAW) Field Descriptions (continued)

Bit	Field	Value	Description
9	AAS		Address recognized as slave IRQ status. I2C mode only. This read only bit is set to 1 by the device when it has recognized its own slave address (or one of the alternative own addresses), or an address of all zeros (8 bits). When this bit is set to 1 by the core, an interrupt is signaled to the local host if the interrupt was enabled. This bit can be cleared in 2 ways: • If the interrupt was enabled, it will be cleared by writing 1 into this register (writing 0 has no effect) • If the interrupt was not enabled, the AAS bit is reset to 0 by restart or stop
		0	No action
		1	Address recognized
			Value after reset is low.
8	BF		I2C mode only. This read only bit is set to 1 by the device when the I2C bus became free (after a transfer is ended on the bus – stop condition detected). This interrupt informs the Local Host that it can initiate its own I2C transfer on the bus. When this bit is set to 1 by the core, an interrupt is signaled to the local host if the interrupt was enabled. The CPU can only clear this bit by writing a 1 into this register. Writing 0 has no effect.
		0	No action
		1	Bus Free
			Value after reset is low.
7	AERR		Access Error IRQ status. I2C mode only. This read/clear only bit is set to 1 by the device if an OCP write access is performed to I2C_DATA while the TX FIFO is full or if an OCP read access is performed to the I2C_DATA while the RX FIFO is empty. Note that, when the RX FIFO is empty, a read access will return to the previous read data value. When the TX FIFO is full, a write access is ignored. In both events, the FIFO pointers will not be updated. When this bit is set to 1 by the core, an interrupt is signaled to the local host if the interrupt was enabled. The CPU can only clear this bit by writing a 1 into this register. Writing 0 has no effect.
		0	No action
		1	Access Error
			Value after reset is low.
6	STC		Start Condition IRQ status. I2C mode only. This read/clear only bit is set to 1 by the device if previously the module was in idle mode and a start condition was asynchronously detected on the I2C Bus and signalized with an Wakeup (if the I2C_SYSC.ClockActivity allows the system clock to be cut-off). When the Active Mode will be restored and the interrupt generated, this bit will indicate the reason of the wakeup. **Note 1:** The corresponding interrupt for this bit should be enabled only if the module was configured to allow the possibility of cutting-off the system clock while in Idle State (I2C_SYSC.ClockActivity = 00 or 01). **Note 2:** The first transfer (corresponding to the detected start condition) will be lost (not taken into account by the module) and it will be used only for generating the WakeUp enable for restoring the Active Mode of the module. On the I2C line, the external master which generated the transfer will detect this behavior as a not acknowledge to the address phase and will possibly restart the transfer. The CPU can only clear this bit by writing a 1 into this register. Writing 0 has no effect.
		0	No action
		1	Start Condition detected
			Value after reset is low.

Table 20-13. I2C Status Raw Register (I2C_IRQSTATUS_RAW) Field Descriptions (continued)

Bit	Field	Value	Description
5	GC		General call IRQ status. Set to '1' by core when General call address detected and interrupt signaled to MPUSS. Write '1' to clear. I2C mode only. This read/clear only bit is set to 1 by the device if it detects the address of all zeros (8 bits) (general call). When this bit is set to 1 by the core, an interrupt is signaled to the local host if the interrupt was enabled. The CPU can only clear this bit by writing a 1 into this register. Writing 0 has no effect. **Note:** When this bit is set to 1, AAS also reads as 1.
		0	No general call detected
		1	General call address detected
			Value after reset is low.
4	XRDY		Transmit data ready IRQ status. Set to '1' by core when transmitter and when new data is requested. When set to '1' by core, an interrupt is signaled to MPUSS. Write '1' to clear. Transmit mode only (I2C mode). This read/clear only bit (XRDY) is set to 1 when the I2C peripheral is a master or slave transmitter, the CPU needs to send data through the I2C bus, and the module (transmitter) requires new data to be served. Note that a master transmitter requests new data if the FIFO TX level is below the threshold (TXTRSH) and the required amount of data remained to be transmitted (I2C_BUFSTAT.TXSTAT) is greater than the threshold. A slave transmitter requests new data when the FIFO TX level is below the threshold (if TXTRSH > 1), or anytime there is a read request from external master (for each acknowledge received from the master), if TXTRSH = 1. When this bit is set to 1 by the core, an interrupt is signaled to the local host if the interrupt was enabled. The CPU can also poll this bit (refer to the FIFO Management subsection for details about XRDY generation). The CPU can only clear this bit by writing a 1 into this register. Writing 0 has no effect. **Note:** If the DMA transmit mode is enabled (I2C_BUF.XDMA_EN is set, together with I2C_DMATXENABLE_SET), this bit is forced to 0 and no interrupt will be generated; instead, a DMA TX request to the main DMA controller of the system is generated.
		0	Transmission ongoing
		1	Transmit data ready
			Value after reset is low.
3	RRDY		Receive mode only (I2C mode). This read/clear only RRDY is set to 1 when the RX FIFO level is above the configured threshold (RXTRSH). When this bit is set to 1 by the core, CPU is able to read new data from the I2C_DATA register. If the corresponding interrupt was enabled, an interrupt is signaled to the local host. The CPU to read the received data in I2C_DATA register can also poll this bit (refer to the FIFO Management subsection for details about RRDY generation). The CPU can only clear this bit by writing a 1 into this register. A write 0 has no effect. If the DMA receive mode is enabled (I2C_BUF.RDMA_EN is set, together with I2C_DMARXENABLE_SET), this bit is forced to 0 and no interrupt will be generated; instead a DMA RX request to the main DMA controller of the system is generated.
		0	Receive FIFO threshold not reached
		1	Receive data ready for read (RX FIFO threshold reached)
			Value after reset is low.

Table 20-13. I2C Status Raw Register (I2C_IRQSTATUS_RAW) Field Descriptions (continued)

Bit	Field	Value	Description
2	ARDY		I2C mode only. This read/clear only bit, when set to 1, indicates that the previously programmed data and command (receive or transmit, master or slave) has been performed and status bit has been updated. The CPU uses this flag to let it know that the I2C registers are ready to be accessed again. The CPU can only clear this bit by writing a 1 into this register. A write 0 has no effect. **Mode** / **Others** / **ARDY Set Condition** I2C Master transmit / STP = 1 / DCOUNT = 0 I2C Master receive / STP = 1 / DCOUNT = 0 and receiver FIFO empty I2C Master transmit / STP = 0 / DCOUNT passed 0 I2C Master receive / STP = 0 / DCOUNT passed 0 and receiver FIFO empty I2C Master transmit / - / Stop or restart condition received from master I2C Slave receive / - / Stop or restart condition and receiver FIFO empty
		0	No action
		1	Access ready
			Value after reset is low.
1	NACK		No acknowledgement IRQ status. Bit is set when No Acknowledge has been received, an interrupt is signaled to MPUSS. Write '1' to clear this bit. I2C mode only. The read/clear only No Acknowledge flag bit is set when the hardware detects No Acknowledge has been received. When a NACK event occurs on the bus, this bit is set to 1, the core automatically ends the transfer and clears the MST/STP bits in the I2C_CON register and the I2C becomes a slave. Clearing the FIFOs from remaining data might be required. The CPU can only clear this bit by writing a 1 into this register. Writing 0 has no effect.
		0	Normal operation
		1	Not Acknowledge detected
			Value after reset is low.
0	AL		Arbitration lost IRQ status. This bit is automatically set by the hardware when it loses the Arbitration in master transmit mode, an interrupt is signaled to MPUSS. During reads, it always returns 0. I2C mode only. The read/clear only Arbitration Lost flag bit is set to 1 when the device (configured in master mode) detects it has lost an arbitration (in Address Phase). This happens when two or more masters initiate a transfer on the I2C bus almost simultaneously or when the I2C attempts to start a transfer while BB (bus busy) is 1. When this is set to 1 due to arbitration lost, the core automatically clears the MST/STP bits in the I2C_CON register and the I2C becomes a slave receiver. The CPU can only clear this bit by writing a 1 to this register. Writing 0 has no effect.
		0	Normal operation
		1	Arbitration lost detected
			Value after reset is low.

20.4.6 I2C Status Register (I2C_IRQSTATUS)

This register provides core status information for interrupt handling, showing all active and enabled events and masking the others. The fields are read-write. Writing a 1 to a bit will clear it to 0, that is, clear the IRQ. Writing a 0 will have no effect, that is, the register value will not be modified. Only enabled, active events will trigger an actual interrupt request on the IRQ output line.

For all the internal fields of the I2C_IRQSTATUS register, the descriptions given in the I2C_IRQSTATUS_RAW subsection are valid.

20.4.9 I2C Wakeup Enable Register (I2C_WE)

Every 1-bit field in the I2C_WE register enables a specific (synchronous) IRQ request source to generate an asynchronous wakeup (on the appropriate swakeup line). When a bit location is set to 1 by the local host, a wakeup is signaled to the local host if the corresponding event is captured by the core of the I2C controller. Value after reset is low (all bits).

NOTE:

- There is no need for an Access Error WakeUp event, since this event occurs only when the module is in Active Mode (for OCP accesses to FIFO) and is signaled by an interrupt.
- With the exception of Start Condition WakeUp, which is asynchronously detected when the Functional clock is turned-off, all the other WakeUp events require the Functional (System) clock to be enabled.

Table 20-17. I2C Wakeup Enable Register (I2C_WE) Field Descriptions

Bit	Field	Value	Description
31-15	Reserved	0	Reserved
14	XDR_WE		Transmit draining wakeup enable. This read/write bit is used to enable or disable wakeup signal generation when I2C module is in idle mode, the TX FIFO level is below the threshold and the amount of data left to be transferred is less than TXTRSH value. This allows for the module to inform the CPU that it can check the amount of data to be written to the FIFO.
		0	Transmit draining wakeup disabled
		1	Transmit draining wakeup enabled
13	RDR_WE		Receive draining wakeup enable. This read/write bit is used to enable or disable wakeup signal generation when I2C is in idle mode, configured as a receiver, and it has detected a stop condition on the bus but the RX FIFO threshold is not reached (but the FIFO is not empty). This allows for the module to inform the CPU that it can check the amount of data to be transferred from the FIFO.
		0	Receive draining wakeup disabled

Table 20-17. I2C Wakeup Enable Register (I2C_WE) Field Descriptions (continued)

Bit	Field	Value	Description
9	AAS_WE		Address as slave IRQ wakeup enable. This read/write bit is used to enable or disable wakeup signal generation when I2C module is in idle mode, and external master addresses the I2C module as a slave. This allows for the module to inform the CPU that it can check which of the own addresses was used by the external master to access the I2C core.
		0	Addressed as slave wakeup disabled
		1	Addressed as slave wakeup enabled
8	BF_WE		Bus free IRQ wakeup enable. This read/write bit is used to enable or disable wakeup signal generation when I2C module is in idle mode and the I2C bus became free. This allows for the module to inform the CPU that it can initiate its own transfer on the I2C line.
		0	Bus Free wakeup disabled
		1	Bus Free wakeup enabled
7	Reserved	0	Reserved
6	STC_WE		Start condition IRQ wakeup set. This read/write bit is used to enable or disable wakeup signal generation when I2C module is in idle mode (with the functional clock inactive) and a possible start condition is detected on the I2C line. The STC WakeUp is generated only if the I2C_SYSC.ClockActivity field indicates that the functional clock can be disabled. Note that if the functional clock is not active, the start condition is asynchronously detected (no filtering and synchronization is used). For this reason, it is possible that the signalized start condition to be a glitch. If the functional clock cannot be disabled (I2C_SYSC.ClockActivity = 10 or 11), the programmer should not enable this wakeup, since the module has other synchronously detected WakeUp event that might be used to exit from idle mode, only if the detected transfer is accessing the I2C module.
		0	Start condition wakeup disabled
		1	Start condition wakeup enabled
5	GC_WE		General call IRQ wakeup enable. This read/write bit is used to enable or disable wakeup signal generation when I2C module is in idle mode and a general call is received on I2C line.
		0	General call wakeup disabled
		1	General call wakeup enabled
4	Reserved	0	Reserved
3	DRDY_WE		Receive/Transmit data ready IRQ wakeup enable. This read/write bit is used to enable or disable wakeup signal generation when I2C module is involved into a long transfer and no more registers accesses are performed on the interface (for example module are set in F/S I2C master transmitter mode and FIFO is full). If in the middle of such a transaction, the FIFO buffer needs more data to be transferred, CPU must be informed to write (in case of transmitter mode) or read (if receiver mode) in/from the FIFO.
		0	Transmit/receive data ready wakeup disabled
		1	Transmit/receive data ready wakeup enabled
2	ARDY_WE		Register access ready IRQ wakeup enable. This read/write bit is used to enable or disable wakeup signal generation when I2C module is involved into a long transfer and no more registers accesses are performed on the interface (for example the module is set in F/S I2C master transmitter mode and FIFO is full). If the current transaction is finished, the module needs to inform CPU about transmission completion.
		0	Register access ready wakeup disabled
		1	Register access ready wakeup enabled
1	NACK_WE		No acknowledgment IRQ wakeup enable. This read/write bit is used to enable or disable wakeup signal generation when I2C module is involved into a long transfer and no more registers accesses are performed on the interface (for example the module is set in F/S I2C master transmitter mode and FIFO is full). If in the middle of such of a transaction a Not Acknowledgment event is raised, the module needs to inform CPU about transmission error.
		0	Not Acknowledge wakeup disabled
		1	Not Acknowledge wakeup enabled

Table 20-17. I2C Wakeup Enable Register (I2C_WE) Field Descriptions (continued)

Bit	Field	Value	Description
0	AL_WE		Arbitration lost IRQ wakeup enable. This read/write bit is used to enable or disable wakeup signal generation when I2C module is configured as a master and it loses the arbitration. This wake up is very useful when the module is configured as a master transmitter, all the necessary data is provided in the FIFO Tx, STT is enabled and the module enters in Idle Mode. If the module loses the arbitration, an Arbitration Lost event is raised and the module needs to inform CPU about transmission error. **Note:** The AL wakeup must be enabled only for multimaster communication. If the AL_WE is not enabled and the scenario described above occurs, the module will not be able to inform the CPU about the state of the transfer and it will be blocked in an undetermined state.
		0	Arbitration lost wakeup disabled
		1	Arbitration lost wakeup enabled

20.4.10 Receive DMA Enable Set Register (I2C_DMARXENABLE_SET)

The 1-bit field enables a receive DMA request. Writing a 1 to this field will set it to 1. Writing a 0 will have no effect, that is, the register value is not modified. Note that the I2C_BUF.RDMA_EN field is the global (slave) DMA enabler, and that it is disabled by default. The I2C_BUF.RDMA_EN field should also be set to 1 to enable a receive DMA request.

Table 20-25. Buffer Configuration Register (I2C_BUF) Field Descriptions (continued)

Bit	Field	Value	Description
13-8	RXTRSH	0-3Fh	Threshold value for FIFO buffer in RX mode. The receive threshold value is used to specify the trigger level for data receive transfers. The value is specified from the OCP point of view.
		0	Receive Threshold value = 1
		1	Receive Threshold value = 2
		-	
		-	
		3Fh	Receive Threshold value = 64
			Value after reset is 00h.
			For the FIFO management description, see the FIFO Management subsection.
			Note1: programmed threshold cannot exceed the actual depth of the FIFO.
			Note2: the threshold must not be changed while a transfer is in progress (after STT was configured or after the module was addressed as a slave).
7	XDMA_EN		Transmit DMA channel enable. When this bit is set to 1, the transmit DMA channel is enabled and the transmit data ready status (I2C_IRQSTATUS_RAW: XRDY) bit is forced to 0 by the core.
		0	Transmit DMA channel disabled
		1	Transmit DMA channel enabled
			Value after reset is low.
6	TXFIFO_CLR		Transmit FIFO clear. When set, transmit FIFO is cleared (hardware reset for TX FIFO). This bit is automatically reset by the hardware. During reads, it always returns 0.
		0	Normal mode
		1	Tx FIFO is reset
			Value after reset is low.
5-0	TXTRSH	0-3Fh	Threshold value for FIFO buffer in TX mode. The Transmit Threshold value is used to specify the trigger level for data transfers. The value is specified from the OCP point of view.
		0	Transmit Threshold value = 1
		1	Transmit Threshold value = 2
		-	
		-	
		3Fh	Transmit Threshold value = 64
			Value after reset is 00h
			Note1: programmed threshold cannot exceed the actual depth of the FIFO.
			Note2: the threshold must not be changed while a transfer is in progress (after STT was configured or after the module was addressed as a slave).

20.4.18 Data Counter Register (I2C_CNT)

CAUTION

During an active transfer phase (between STT has been set to 1 and receiving of ARDY), no modification must be done in this register. Changing it may result in an unpredictable behavior.

This read/write register is used to control the numbers of bytes in the I2C data payload.

Figure 20-33. Data Counter Register (I2C_CNT)

31 – 16	15 – 0
Reserved	DCOUNT
R-0	R/W-0

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 20-26. Data Counter Register (I2C_CNT) Field Descriptions

Bit	Field	Value	Description
31-16	Reserved	0	Reserved
15-0	DCOUNT	0-FFFFh	Data count. I2C Master Mode only (receive or transmit; F/S). This 16-bit countdown counter decrements by 1 for every byte received or sent through the I2C interface. A write initializes DCOUNT to a saved initial value. A read returns the number of bytes that are yet to be received or sent. A read into DCOUNT returns the initial value only before a start condition and after a stop condition. When DCOUNT reaches 0, the core generates a stop condition if a stop condition was specified (I2C_CON.STP = 1) and the ARDY status flag is set to 1 in the I2C_IRQSTATUS_RAW register. Note that DCOUNT must not be reconfigured after I2C_CON.STT was enabled and before ARDY is received. **Note1:** In case of I2C mode of operation, if I2C_CON.STP = 0, then the I2C asserts SCL = 0 when DCOUNT reaches 0. The CPU can then reprogram DCOUNT to a new value and resume sending or receiving data with a new start condition (restart). This process repeats until the CPU sets to 1 the I2C_CON.STP bit. The ARDY flag is set each time DCOUNT reaches 0 and DCOUNT is reloaded to its initial value.
		0	Data counter = 65536 bytes (216)
		1	Data counter = 1 bytes
		-	
		-	
		FFFFh	Data counter = 65535 bytes (216 - 1) Values after reset are low (all 16 bits). **Note2:** Since for DCOUNT = 0, the transfer length is 65536, the module does not allow the possibility to initiate zero data bytes transfers.

Copyright © 2011, Texas Instruments Incorporated

20.4.19 Data Access Register (I2C_DATA)

This register is the entry point for the local host to read data from or write data to the FIFO buffer.

Figure 20-34. Data Access Register (I2C_DATA)

31 – 8	7 – 0
Reserved	DATA
R-0	R/W-x

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 20-27. Data Access Register (I2C_DATA) Field Descriptions

Bit	Field	Value	Description
31-8	Reserved	0	Reserved
7-0	DATA	0-FFh	Transmit/Receive data FIFO endpoint. When read, this register contains the received I2C data. When written, this register contains the byte value to transmit over the I2C data. In SYSTEST loop back mode (I2C_SYSTEST: TMODE = 11), this register is also the entry/receive point for the data. Values after reset are unknown (all 8-bits). **Note:** A read access, when the buffer is empty, returns the previous read data value. A write access, when the buffer is full, is ignored. In both events, the FIFO pointers are not updated and an Access Error (AERR) Interrupt is generated.

Table 20-28. I2C Configuration Register (I2C_CON) Field Descriptions

Bit	Field	Value	Description
31-16	Reserved	0	Reserved
15	I2C_EN		I2C module enable. When this bit is cleared to 0, the I2C controller is not enabled and reset. When 0, receive and transmit FIFOs are cleared and all status bits are set to their default values. All configuration registers (I2C_IRQENABLE_SET, I2C_IRQWAKE_SET, I2C_BUF, I2C_CNT, I2C_CON, I2C_OA, I2C_SA, I2C_PSC, I2C_SCLL and I2C_SCLH) are not reset, they keep their initial values and can be accessed. The CPU must set this bit to 1 for normal operation.
		0	Controller in reset. FIFO are cleared and status bits are set to their default value.
		1	Module enabled
			Value after reset is low.
14	Reserved	0	Reserved
13-12	OPMODE		Operation mode selection. These two bits select module operation mode.
		0h	I2C Fast/Standard mode
		1h	Reserved
		2h	Reserved
		3h	Reserved
			Value after reset is 00.
11	STB		Start byte mode (I2C master mode only). The start byte mode bit is set to 1 by the CPU to configure the I2C in start byte mode (I2C_SA = 0000 0001). See the Philips I2C spec for more details [1].
		0	Normal mode
		1	Start byte mode
			Value after reset is low.
10	MST		Master/slave mode (I2C mode only). When this bit is cleared, the I2C controller is in the slave mode and the serial clock (SCL) is received from the master device. When this bit is set, the I2C controller is in the master mode and generates the serial clock.
			Note: This bit is automatically cleared at the end of the transfer on a detected stop condition, in case of arbitration lost or when the module is configured as a master but addressed as a slave by an external master.
		0	Slave mode
		1	Master mode
			Value after reset is low.

Table 20-28. I2C Configuration Register (I2C_CON) Field Descriptions (continued)

Bit	Field	Value	Description
9	TRX		Transmitter/receiver mode (i2C master mode only). When this bit is cleared, the I2C controller is in the receiver mode and data on data line SDA is shifted into the receiver FIFO and can be read from I2C_DATA register. When this bit is set, the I2C controller is in the transmitter mode and the data written in the transmitter FIFO via I2C_DATA is shifted out on data line SDA.
		0	Receiver mode
		1	Transmitter mode
			Value after reset is low.
			The operating modes are defined as follows:
			MST / **TRX** / **Operating Modes**
			0 / x / Slave receiver
			0 / x / Slave transmitter
			1 / 0 / Master receiver
			1 / 1 / Master transmitter
8	XSA		Expand slave address. (I2C mode only). When set, this bit expands the slave address to 10-bit.
		0	7-bit address mode
		1	10-bit address mode
			Value after reset is low.
7	XOA0		Expand own address 0. (I2C mode only). When set, this bit expands the base own address (OA0) to 10-bit.
		0	7-bit address mode
		1	10-bit address mode
			Value after reset is low.
6	XOA1		Expand own address 1. (I2C mode only). When set, this bit expands the first alternative own address (OA1) to 10-bit.
		0	7-bit address mode
		1	10-bit address mode
			Value after reset is low.
5	XOA2		Expand own address 2. (I2C mode only). When set, this bit expands the second alternative own address (OA2) to 10-bit.
		0	7-bit address mode. (I2C mode only).
		1	10-bit address mode
			Value after reset is low.
4	XOA3		Expand own address 3. When set, this bit expands the third alternative own address (OA3) to 10-bit.
		0	7-bit address mode
		1	10-bit address mode
			Value after reset is low.
3-2	Reserved	0	Reserved
1	STP		Stop condition (I2C master mode only). This bit can be set to a 1 by the CPU to generate a stop condition. It is reset to 0 by the hardware after the stop condition has been generated. The stop condition is generated when DCOUNT passes 0.
			When this bit is not set to 1 before the end of the transfer (DCOUNT = 0), the stop condition is not generated and the SCL line is hold to 0 by the master, which can re-start a new transfer by setting the STT bit to 1.
		0	No action or stop condition detected
		1	Stop condition queried
			Value after reset is low

Table 20-28. I2C Configuration Register (I2C_CON) Field Descriptions (continued)

Bit	Field	Value	Description
0	STT		Start condition (I2C master mode only). This bit can be set to a 1 by the CPU to generate a start condition. It is reset to 0 by the hardware after the start condition has been generated. The start/stop bits can be configured to generate different transfer formats.
		0	No action or start condition detected
		1	Start condition queried
			Value after reset is low.

STT	STP	Conditions	Bus Activities
1	0	Start	S-A-D
0	1	Stop	P
1	1	Start-Stop (DCOUNT= n)	S-A-D..(n)..D-P
1	0	Start (DCOUNT= n)	S-A-D..(n)..D

Note: DCOUNT is data count value in I2C_CNT register.

20.4.21 I2C Own Address Register (I2C_OA)

CAUTION

During an active transfer phase (between STT has been set to 1 and receiving of ARDY), no modification must be done in this register. Changing it may result in an unpredictable behavior.

This register is used to specify the module's base I2C 7-bit or 10-bit address (base own address).

Figure 20-36. I2C Own Address Register (I2C_OA)

31 – 10	9 – 0
Reserved	OA
R-0	R/W-0

LEGEND: R/W = Read/Write; R = Read only; *-n* = value after reset

Table 20-29. I2C Own Address Register (I2C_OA) Field Descriptions

Bit	Field	Value	Description
31-10	Reserved	0	Reserved
9-0	OA	0-3FFh	Own address. This field specifies either: • A 10-bit address coded on OA [9:0] when XOA (Expand Own Address, I2C_CON[7]) is set to 1. • A 7-bit address coded on OA [6:0] when XOA (Expand Own Address, I2C_CON[7]) is cleared to 0. In this case, OA [9:7] bits must be cleared to 000 by application software. Value after reset is low (all 10 bits).

20.4.22 I2C Slave Address Register (I2C_SA)

CAUTION

During an active transfer phase (between STT has been set to 1 and receiving of ARDY), no modification must be done in this register. Changing it may result in an unpredictable behavior.

This register is used to specify the addressed I2C module 7-bit or 10-bit address (slave address).

Figure 20-37. I2C Own Address Register (I2C_SA)

20.4.23 I2C Clock Prescaler Register (I2C_PSC)

CAUTION

During an active mode (I2C_EN bit in I2C_CON register is set to 1), no modification must be done in this register. Changing it may result in an unpredictable behavior.

This register is used to specify the internal clocking of the I2C peripheral core.

Figure 20-38. I2C Own Address Register (I2C_PSC)

31 – 8	7 – 0
Reserved	PSC
R-0	R/W-0

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 20-31. I2C Clock Prescaler Register (I2C_PSC) Field Descriptions

Bit	Field	Value	Description
31-8	Reserved	0	Reserved
7-0	PSC	0-FFh	Fast/Standard mode prescale sampling clock divider value. The core uses this 8-bit value to divide the system clock (SCLK) and generates its own internal sampling clock (ICLK) for Fast and Standard operation modes. The core logic is sampled at the clock rate of the system clock for the module divided by (PSC + 1).
		0h	Divide by 1
		1h	Divide by 2
		-	
		-	
		FFh	Divide by 256
			Value after reset is low (all 8 bits).

20.4.24 I2C SCL Low Time Register (I2C_SCLL)

CAUTION

During an active mode (I2C_EN bit in I2C_CON register is set to 1), no modification must be done in this register. Changing it may result in an unpredictable behavior.

This register is used to determine the SCL low time value when master.

Figure 20-40. I2C SCL Low Time Register (I2C_SCLL)

20.4.26 System Test Register (I2C_SYSTEST)

CAUTION

Never enable this register for normal I2C operation

This register is used to facilitate system-level tests by overriding some of the standard functional features of the peripheral. It allows testing of SCL counters, controlling the signals that connect to I/O pins, or creating digital loop-back for self-test when the module is configured in system test (SYSTEST) mode. It also provides stop/non-stop functionality in the debug mode.

Figure 20-42. System Test Register (I2C_SYSTEST)

31							16
Reserved							
R-0							
15	14	13	12	11	10	9	8

R/W-0	R/W-0	R/W-0		R/W-0	R-0		R-1
7	6	5	4	3	2	1	0
SCL_O_FUNC	SDA_I_FUNC	SDA_O_FUNC	Reserved	SCL_I	SCL_O	SDA_I	SDA_O
R-1	R-1	R-1	R-0	R-0	R-0	R-0	R-0

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 20-34. System Test Register (I2C_SYSTEST) Field Descriptions

Bit	Field	Value	Description
31-16	Reserved	0	Reserved
15	ST_EN		System test enable. This bit must be set to 1 to permit other system test registers bits to be set.
		0	Normal mode. All others bits in register are read only.
		1	System test enabled. Permit other system test registers bits to be set.
			Value after reset is low.
14	FREE		Free running mode (on breakpoint). This bit is used to determine the state of the I2C controller when a breakpoint is encountered in the HLL debugger.
			Note: This bit can be set independently of ST_EN value. FREE = 0: the I2C controller stops immediately after completion of the on-going bit transfer. Stopping the transfer is achieved by forcing the SCL line low. Note that in this case there will be no status register updates.
			FREE = 1: the I2C interface runs free. When Suspend indication will be asserted, there will be no accesses on the OCP Interface (the CPU is in debug mode) and consequently the FIFOs will reach full/empty state (according to RX or TX modes) and the I2C SDA line will be kept low. Note that the status registers will be updated, but no DMA, IRQ or WakeUp will be generated.
			The status registers likely to be updated in this mode are: I2C_IRQSTATUS_RAW.XRDY, I2C_IRQSTATUS_RAW.RRDY, I2C_IRQSTATUS_RAW.XUDF, I2C_IRQSTATUS_RAW.ROVR, I2C_IRQSTATUS_RAW.ARDY and I2C_IRQSTATUS_RAW.NACK.
		0	Stop mode (on breakpoint condition). If Master mode, it stops after completion of the on-going bit transfer. In slave mode, it stops during the phase transfer when 1 byte is completely transmitted/received.
		1	Free running mode
			Value after reset is low.

Table 20-34. System Test Register (I2C_SYSTEST) Field Descriptions (continued)

Bit	Field	Value	Description
13-12	TMODE		Test mode select. In normal functional mode (ST_EN = 0), these bits are don't care. They are always read as 00 and a write is ignored. In system test mode (ST_EN = 1), these bits can be set according to the following table to permit various system tests.
		0	Functional mode (default)
		1h	Reserved
		2h	Test of SCL counters (SCLL, SCLH, PSC). SCL provides a permanent clock with master mode.
		3h	Loop back mode select + SDA/SCL IO mode select
			Values after reset are low (2 bits).
			SCL counter test mode: in this mode, the SCL pin is driven with a permanent clock as if mastered with the parameters set in the I2C_PSC, I2C_SCLL, and I2C_SCLH registers.
			Loop back mode: in the master transmit mode only, data transmitted out of the I2C_DATA register (write action) is received in the same I2C_DATA register via an internal path through the FIFO buffer. The DMA and interrupt requests are normally generated if enabled.
			SDA/SCL IO mode: in this mode, the SCL IO and SDA IO are controlled via the I2C_SYSTEST [5:0] register bits.
11	SSB		Set status bits. Writing 1 into this bit also sets the 6 read/clear-only status bits contained in I2C_IRQSTATUS_RAW register (bits 5:0) to 1. Writing 0 into this bit doesn't clear status bits that are already set; only writing 1 into a set status bit can clear it (see I2C_IRQSTATUS_RAW operation). This bit must be cleared prior attempting to clear a status bit.
		0	No action
		1	Set all interrupt status bits to 1
			Value after reset is low.
10-9	Reserved	0	Reserved
8	SCL_I_FUNC		SCL line input value (functional mode). This read-only bit returns the logical state taken by the SCL line (either 1 or 0). It is active both in functional and test mode
		Read:0	Read 0 from SCL line
		Read:1	Read 1 from SCL line
			Value after reset is low.
7	SCL_O_FUNC		SCL line output value (functional mode). This read-only bit returns the value driven by the module on the SCL line (either 1 or 0). It is active both in functional and test mode.
		Read:0	Driven 0 on SCL line
		Read:1	Driven 1 on SCL line
			Value after reset is low.
6	SDA_I_FUNC		SDA line input value (functional mode). This read-only bit returns the logical state taken by the SDA line (either 1 or 0). It is active both in functional and test mode.
		Read:0	Read 0 from SDA line
		Read:1	Read 1 from SDA line
			Value after reset is low.
5	SDA_O_FUNC		SDA line output value (functional mode). This read-only bit returns the value driven by the module on the SDA line (either 1 or 0). It is active both in functional and test mode.
		Read:0	Driven 0 to SDA line
		Read:1	Driven 1 to SDA line
			Value after reset is low.
4	Reserved	0	Reserved
3	SCL_I		SCL line sense input value. In normal functional mode (ST_EN = 0), this read-only bit always reads 0. In system test mode (ST_EN = 1 & TMODE = 11), this read-only bit returns the logical state taken by the SCL line (either 1 or 0).
		Read:0	Read 0 from SCL line
		Read:1	Read 1 from SCL line
			Value after reset is low.

Table 20-35. I2C Buffer Status Register (I2C_BUFSTAT) Field Descriptions

Bit	Field	Value	Description
31-16	Reserved	0	Reserved
15-14	FIFODEPTH		Internal FIFO buffers depth. This read-only bit indicates the internal FIFO buffer depth.
		0	8-bytes FIFO
		1h	16-bytes FIFO
		2h	32-bytes FIFO
		3h	64-bytes FIFO
			Value after reset is given by the boundary module generic parameter.
13-8	RXSTAT	0-3Fh	RX buffer status. This read-only field indicates the number of bytes to be transferred from the FIFO at the end of the I2C transfer (when RDR is asserted). It corresponds to the level indication of the RX FIFO (number of written locations).
			Value after reset is 0.
7-6	Reserved	0	Reserved
5-0	TXSTAT	0-3Fh	TX buffer status. This read-only field indicates the number of data bytes still left to be written in the TX FIFO (it's equal with the initial value of I2C_CNT.DCOUNT minus the number of data bytes already written in the TX FIFO through the OCP Interface).
			Value after reset is equal with 0.

Multichannel Audio Serial Port (McASP)

This chapter describes the McASP of the device.

Topic **Page**

21.1 Introduction **2670**
21.2 Integration **2672**
21.3 Functional Description **2674**
21.4 McASP Registers **2717**

DRAFT ONLY

21.1 Introduction

21.1.1 Purpose of the Peripheral

The multichannel audio serial port (McASP) functions as a general-purpose audio serial port optimized for the needs of multichannel audio applications. The McASP is useful for time-division multiplexed (TDM) stream, Inter-Integrated Sound (I2S) protocols, and intercomponent digital audio interface transmission (DIT). The McASP consists of transmit and receive sections that may operate synchronized, or completely independently with separate master clocks, bit clocks, and frame syncs, and using different transmit modes with different bit-stream formats. The McASP module also includes serializers that can be individually enabled to either transmit or receive.

21.1.2 Features

Features of the McASP include:

- Two independent clock generator modules for transmit and receive.
  - Clocking flexibility allows the McASP to receive and transmit at different rates. For example, the McASP can receive data at 48 kHz but output up-sampled data at 96 kHz or 192 kHz.
- Independent transmit and receive modules, each includes:
  - Programmable clock and frame sync generator.
  - TDM streams from 2 to 32, and 384 time slots.
  - Support for time slot sizes of 8, 12, 16, 20, 24, 28, and 32 bits.
  - Data formatter for bit manipulation.
- Individually assignable serial data pins (up to 6 pins).
- Glueless connection to audio analog-to-digital converters (ADC), digital-to-analog converters (DAC), codec, digital audio interface receiver (DIR), and S/PDIF transmit physical layer components.
- Wide variety of I2S and similar bit-stream format.
- Integrated digital audio interface transmitter (DIT) supports (up to 10 transmit pins):
  - S/PDIF, IEC60958-1, AES-3 formats.
  - Enhanced channel status/user data RAM.
- 384-slot TDM with external digital audio interface receiver (DIR) device.
  - For DIR reception, an external DIR receiver integrated circuit should be used with I2S output format and connected to the McASP receive section.
- Extensive error checking and recovery.
  - Transmit underruns and receiver overruns due to the system not meeting real-time requirements.
  - Early or late frame sync in TDM mode.
  - Out-of-range high-frequency master clock for both transmit and receive.
  - External error signal coming into the AMUTEIN input.
  - DMA error due to incorrect programming.

21.1.3 Protocols Supported

The McASP supports a wide variety of protocols.

- Transmit section supports:
  - Wide variety of I2S and similar bit-stream formats.
  - TDM streams from 2 to 32 time slots.
  - S/PDIF, IEC60958-1, AES-3 formats.
- Receive section supports:
  - Wide variety of I2S and similar bit-stream formats.
  - TDM streams from 2 to 32 time slots.
  - TDM stream of 384 time slots specifically designed for easy interface to external digital interface

DRAFT ONLY

receiver (DIR) device transmitting DIR frames to McASP using the I2S protocol (one time slot for each DIR subframe).

The transmit and receive sections may each be individually programmed to support the following options on the basic serial protocol:

- Programmable clock and frame sync polarity (rising or falling edge): ACLKR/X, AHCLKR/X, and AFSR/X.
- Slot length (number of bits per time slot): 8, 12, 16, 20, 24, 28, 32 bits supported.
- Word length (bits per word): 8, 12, 16, 20, 24, 28, 32 bits; always less than or equal to the time slot length.
- First-bit data delay: 0, 1, 2 bit clocks.
- Left/right alignment of word inside slot.
- Bit order: MSB first or LSB first.
- Bit mask/pad/rotate function.
  - Automatically aligns data internally in either Q31 or integer formats.
  - Automatically masks nonsignificant bits (sets to 0, 1, or extends value of another bit).

In DIT mode for McASP, additional features of the transmitter are:

- Transmit-only mode 384 time slots (subframe) per frame.
- Bi-phase encoded 3.3 V output.
- Support for consumer and professional applications.
- Channel status RAM (384 bits).
- User data RAM (384 bits).
- Separate valid bit (V) for subframe A, B.

In I2S mode, the transmit and receive sections can support simultaneous transfers on up to all serial data pins operating as 192 kHz stereo channels.

In DIT mode, the transmitter can support a 192 kHz frame rate (stereo) on up to all serial data pins simultaneously (note that the internal bit clock for DIT runs two times faster than the equivalent bit clock for I2S mode, due to the need to generate Biphase Mark Encoded Data).

21.1.4 Unsupported McASP Features

The unsupported McASP features in this device include the following:

- AXR[9:4] — Signals are not pinned out
- AMUTE — Not connected
- AMUTEIN — Not connected

21.2 Integration

The device contains two instantiations of the McASP subsystem: McASP0 and McASP1. The McASP subsystem includes a McASP peripheral, and transmit/receive buffers.

Each McASP is configured with 10 serializers but only serializers 0–3 are pinned out on this device.

Figure 21-1. McASP0–1 Integration

21.2.1 McASP Connectivity Attributes

The general connectivity attributes for the McASP modules are summarized in Table 21-1

Table 21-1. McASP Connectivity Attributes

Attributes	Type
Power Domain	Peripheral Domain
Clock Domain	PD_PER_L3S_GCLK (OCP Clock) PD_PER_MCASP_FCLK (Aux Clock)
Reset Signals	PER_DOM_RST_N
Idle/Wakeup Signals	Smart Idle
Interrupt Requests	1 Transmit Interrupt x_intr_pend - to MPU subsystem and PRUSS 1 Receive Interrupt r_intr_pend - to MPU subsystem and PRUSS
DMA Requests	2 DMA requests to EDMA
Physical Address	L3 Slow slave port (data) L4 Peripheral slave port (CFG)

21.2.2 McASP Clock and Reset Management

The McASP module uses functional clocks either generated internally (master mode) or supplied from its serial interface (slave mode). The internal interconnect interface clock is used for the module internal OCP interface. Internal registers select the source of the functional clocks and the applied divider ratio.

Table 21-2. McASP Clock Signals

Clock Signal	Max Freq	Reference / Source	Comments
ocp_clk Interface clock	100 MHz	CORE_COLKOUTM4 / 2	pd_per_l3s_gclk From PRCM
auxclk Functional clock	24 MHz	CLK_M_OSC	pd_per_mcasp_gfclk From PRCM

21.2.3 McASP Pin List

The McASP external interface signals are shown in Table 21-3.

Table 21-3. McASP Pin List

Pin	Type	Description
McASP*x*_AXR[3:0]	I/O	Audio transmit/receive pin
McASP*x*_ACLKX	I/O	Transmit clock
McASP*x*_FSX	I/O	Frame synch for transmit
McASP*x*_AHCLKX	I/O	High speed transmit clock
McASP*x*_ACLKR	I/O	Receive clock
McASP*x*_FSR	I/O	Frame synch for receive
McASP*x*_AHCLKR	I/O	High speed receive clock

21.3 Functional Description

21.3.1 Overview

shows the major blocks of the McASP. The McASP has independent receive/transmit clock generators and frame sync generators, error-checking logic, and up to 6 serial data pins. Refer to the device-specific data manual for the number of data pins available on your device.

All the McASP pins on the device may be individually programmed as general-purpose I/O (GPIO) if they are not used for serial port functions.

The McASP includes the following pins:

- Serializers;
  - Data pins AXRn: Up to 6 pins.
- Transmit clock generator:
  - AHCLKX: McASP transmit high-frequency master clock.
  - ACLKX: McASP transmit bit clock.
- Transmit Frame Sync Generator;
  - AFSX: McASP transmit frame sync or left/right clock (LRCLK).
- Receive clock generator;
  - AHCLKR: McASP receive high-frequency master clock.
  - ACLKR: McASP receive bit clock.
- Receive Frame Sync Generator;
  - AFSR: McASP receive frame sync or left/right clock (LRCLK).
- Mute in/out;
  - AMUTEIN: McASP mute input (from external device).
  - AMUTE: McASP mute output.
  - Data pins AXRn.

21.3.2 Clock and Frame Sync Generators

The McASP clock generators are able to produce two independent clock zones: transmit and receive clock zones. The serial clock generators may be programmed independently for the transmit section and the receive section, and may be completely asynchronous to each other. The serial clock (clock at the bit rate) may be sourced:

- Internally - by passing through two clock dividers off the internal clock source (AUXCLK).
- Externally - directly from ACLKR/X pin.
- Mixed - an external high-frequency clock is input to the McASP on either the AHCLKX or AHCLKR pins, and divided down to produce the bit rate clock.

In the internal/mixed cases, the bit rate clock is generated internally and should be driven out on the ACLKX (for transmit) or ACLKR (for receive) pins. In the internal case, an internally-generated high-frequency clock may be driven out onto the AHCLKX or AHCLKR pins to serve as a reference clock for other components in the system.

The McASP requires a minimum of a bit clock and a frame sync to operate, and provides the capability to reference these clocks from an external high-frequency master clock. In DIT mode, it is possible to use only internally-generated clocks and frame syncs. Both the AUXCLK and System Clock are generated from SYSCLK2 (CLKDIV6 domain).

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

21.3.2.1 Transmit Clock

The transmit bit clock, ACLKX, (Figure 21-2) may be either externally sourced from the ACLKX pin or internally generated, as selected by the CLKXM bit. If internally generated (CLKXM = 1), the clock is divided down by a programmable bit clock divider (CLKXDIV) from the transmit high-frequency master clock (AHCLKX).

Internally, the McASP always shifts transmit data at the rising edge of the internal transmit clock, XCLK, (Figure 21-2). The CLKXP mux determines if ACLKX needs to be inverted to become XCLK. If CLKXP = 0, the CLKXP mux directly passes ACLKX to XCLK. As a result, the McASP shifts transmit data at the rising edge of ACLKX. If CLKXP = 1, the CLKX mux passes the inverted version of ACLKX to XCLK. As a result, the McASP shifts transmit data at the falling edge of ACLKX.

The transmit high-frequency master clock, AHCLKX, may be either externally sourced from the AHCLKX pin or internally generated, as selected by the HCLKXM bit. If internally generated (HCLKXM = 1), the clock is divided down by a programmable high clock divider (HCLKXDIV) from McASP internal clock source AUXCLK. The transmit high-frequency master clock may be (but is not required to be) output on the AHCLKX pin where it is available to other devices in the system.

The transmit clock configuration is controlled by the following registers:

- ACLKXCTL.
- AHCLKXCTL.

Figure 21-2. Transmit Clock Generator Block Diagram

DRAFT ONLY

21.3.2.2 Receive Clock

The receiver also has the option to operate synchronously from the ACLKX and AFSX signals. This is achieved when the ASYNC bit in the transmit clock control register (ACLKXCTL) is cleared to 0 (see Figure 21-3). The receiver may be configured with different polarity (CLKRP) and frame sync data delay options from those options of the transmitter.

The receive clock configuration is controlled by the following registers:

- ACLKRCTL.
- AHCLKRCTL.

Figure 21-3. Receive Clock Generator Block Diagram

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

21.3.2.3 Frame Sync Generator

There are two different modes for frame sync: burst and TDM. A block diagram of the frame sync generator is shown in Figure 21-4. The frame sync options are programmed by the receive and transmit frame sync control registers (AFSRCTL and AFSXCTL). The options are:

- Internally-generated or externally-generated.
- Frame sync polarity: rising edge or falling edge.
- Frame sync width: single bit or single word.
- Bit delay: 0, 1, or 2 cycles before the first data bit.

The transmit frame sync pin is AFSX and the receive frame sync pin is AFSR. A typical usage for these pins is to carry the left/right clock (LRCLK) signal when transmitting and receiving stereo data.

Regardless if the AFSX/AFSR is internally generated or externally sourced, the polarity of AFSX/AFSR is determined by FSXP/FSRP, respectively, to be either rising or falling edge. If FSXP/FSRP = 0, the frame sync polarity is rising edge. If FSRP/FSRP = 1, the frame sync polarity is falling edge.

21.3.2.4 Clocking Examples

Some examples of processes using the McASP clocking and frame flexibility are:

- Receive data from a DVD at 48 kHz, but output up-sampled or decoded audio at 96 kHz or 192 kHz. This could be accomplished by inputting a high-frequency master clock (for example, 512 × receive FS), receiving with an internally-generated bit clock ratio of divide-by-8, and transmitting with an internally-generated bit clock ratio of divide-by-4 or divide-by-2.
- Transmit/receive data based on one sample rate (for example, 44.1 kHz), and transmit/receive data at a different sample rate (for example, 48 kHz).

21.3.3 Memory Map

See the device-specific data manual for information describing the device memory-map.

21.3.4 Signal Descriptions

The signals used on the McASP audio interface are listed in Table 21-4.

Table 21-4. McASP Interface Signals

Pin	I/O/Z	Device Reset (RESET = 0)	Description
		Transmitter Control	
AHCLKX	I/O/Z	Input	Transmit high-frequency master clock
AFSX	I/O/Z	Input	Transmit frame sync or left/right clock (LRCLK)
ACLKX	I/O/Z	Input	Transmit bit clock
		Receiver Control	
AHCLKR	I/O/Z	Input	Receive high-frequency master clock
AFSR	I/O/Z	Input	Receive frame sync or left/right clock (LRCLK)
ACLKR	I/O/Z	Input	Receive bit clock
		Mute	
AMUTE	I/O/Z	Input	Mute output
AMUTEIN	I/O/Z	Input	Mute input
		Data	
AXRn	I/O/Z	Input	TX/RX data pins

21.3.5 Pin Multiplexing

The McASP signals share pins with other processor functions. For detailed information on the McASP pin multiplexing and configuration, see the pin multiplexing information in the device-specific data manual.

21.3.6 Transfer Modes

21.3.6.1 Burst Transfer Mode

The McASP supports a burst transfer mode, which is useful for nonaudio data such as passing control information between two processors. Burst transfer mode uses a synchronous serial format similar to the TDM mode. The frame sync generation is not periodic or time-driven as in TDM mode, but data driven, and the frame sync is generated for each data word transferred.

When operating in burst frame sync mode (Figure 21-5), as specified for transmit (XMOD = 0 in AFSXCTL) and receive (RMOD = 0 in AFSRCTL), one slot is shifted for each active edge of the frame sync signal that is recognized. Additional clocks after the slot and before the next frame sync edge are ignored.

In burst frame sync mode, the frame sync delay may be specified as 0, 1, or 2 serial clock cycles. This is the delay between the frame sync active edge and the start of the slot. The frame sync signal lasts for a single bit clock duration (FRWID = 0 in AFSRCTL, FXWID = 0 in AFSXCTL).

For transmit, when generating the transmit frame sync internally, the frame sync begins when the previous transmission has completed and when all the XBUF[n] (for every serializer set to operate as a transmitter) has been updated with new data.

For receive, when generating the receive frame sync internally, frame sync begins when the previous transmission has completed and when all the RBUF[n] (for every serializer set to operate as a receiver) has been read.

Figure 21-5. Burst Frame Sync Mode

The control registers must be configured as follows for the burst transfer mode. The burst mode specific bit fields are in bold face:

- PFUNC: The clock, frame, data pins must be configured for McASP function.
- PDIR: The clock, frame, data pins must be configured to the direction desired.
- PDOUT, PDIN, PDSET, PDCLR: Not applicable. Leave at default.
- GBLCTL: Follow the initialization sequence in Section 21.3.10.2 to configure this register.
- AMUTE: Not applicable. Leave at default.
- DLBCTL: If loopback mode is desired, configure this register according to Section 21.3.8.5, otherwise leave this register at default.
- DITCTL: DITEN must be left at default 0 to select non-DIT mode. Leave the register at default.
- RMASK/XMASK: Mask desired bits according to Section 21.3.7.2 and Section 21.3.8.3.
- RFMT/XFMT: Program all fields according to data format desired. See Section 21.3.8.3.
- AFSRCTL/AFSXCTL: Clear **RMOD/XMOD** bits to 0 to indicate burst mode. Clear **FRWID/FXWID** bits to 0 for single bit frame sync duration. Configure other fields as desired.
- ACLKRCTL/ACLKXCTL: Program all fields according to bit clock desired. See Section 21.3.2.
- AHCLKRCTL/AHCLKXCTL: Program all fields according to high-frequency clock desired. See Section 21.3.2.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

- RTDM/XTDM: Program RTDMS0/XTDMS0 to 1 to indicate one active slot only. Leave other fields at default.
- RINTCTL/XINTCTL: Program all fields according to interrupts desired.
- RCLKCHK/XCLKCHK: Not applicable. Leave at default.
- SRCTLn: Program SRMOD to inactive/transmitter/receiver as desired. DISMOD is not applicable and should be left at default.
- DITCSRA[n], DITCSRB[n], DITUDRA[n], DITUDRB[n]: Not applicable. Leave at default.

21.3.6.2 Time-Division Multiplexed (TDM) Transfer Mode

The McASP time-division multiplexed (TDM) transfer mode supports the TDM format discussed in .

Transmitting data in the TDM transfer mode requires a minimum set of pins:

- ACLKX - transmit bit clock.
- AFSX - transmit frame sync (or commonly called left/right clock).
- One or more serial data pins, AXRn, whose serializers have been configured to transmit.

The transmitter has the option to receive the ACLKX bit clock as an input, or to generate the ACLKX bit clock by dividing down the AHCLKX high-frequency master clock. The transmitter can either generate AHCLKX internally or receive AHCLKX as an input. See Section 21.3.2.1.

Similarly, to receive data in the TDM transfer mode requires a minimum set of pins:

- ACLKR - receive bit clock.
- AFSR - receive frame sync (or commonly called left/right clock).
- One or more serial data pins, AXRn, whose serializers have been configured to receive.

The receiver has the option to receive the ACLKR bit clock as an input or to generate the ACLKR bit clock by dividing down the AHCLKR high-frequency master clock. The receiver can either generate AHCLKR internally or receive AHCLKR as an input. See Section 21.3.2.2 and Section 21.3.2.3.

The control registers must be configured as follows for the TDM mode. The TDM mode specific bit fields are in bold face:

- PFUNC: The clock, frame, data pins must be configured for McASP function.
- PDIR: The clock, frame, data pins must be configured to the direction desired.
- PDOUT, PDIN, PDSET, PDCLR: Not applicable. Leave at default.
- GBLCTL: Follow the initialization sequence in Section 21.3.10.2 to configure this register.
- AMUTE: Program all fields according to mute control desired.
- DLBCTL: If loopback mode is desired, configure this register according to Section 21.3.8.5, otherwise leave this register at default.
- DITCTL: DITEN must be left at default 0 to select TDM mode. Leave the register at default.
- RMASK/XMASK: Mask desired bits according to Section 21.3.7.2 and Section 21.3.8.3.
- RFMT/XFMT: Program all fields according to data format desired. See Section 21.3.8.3.
- AFSRCTL/AFSXCTL: Set **RMOD/XMOD** bits to 2-32 for TDM mode. Configure other fields as desired.
- ACLKRCTL/ACLKXCTL: Program all fields according to bit clock desired. See Section 21.3.2.
- AHCLKRCTL/AHCLKXCTL: Program all fields according to high-frequency clock desired. See Section 21.3.2.
- RTDM/XTDM: Program all fields according to the time slot characteristics desired.
- RINTCTL/XINTCTL: Program all fields according to interrupts desired.
- RCLKCHK/XCLKCHK: Program all fields according to clock checking desired.
- SRCTLn: Program all fields according to serializer operation desired.
- DITCSRA[n], DITCSRB[n], DITUDRA[n], DITUDRB[n]: Not applicable. Leave at default.

21.3.6.2.1 TDM Time Slots

TDM mode on the McASP can extend to support multiprocessor applications, with up to 32 time slots per frame. For each of the time slots, the McASP may be configured to participate or to be inactive by configuring XTDM and/or RTDM (this allows multiple processors to communicate on the same TDM serial bus).

The TDM sequencer (separate ones for transmit and receive) functions in this mode. The TDM sequencer counts the slots beginning with the frame sync. For each slot, the TDM sequencer checks the respective bit in either XTDM or RTDM to determine if the McASP should transmit/receive in that time slot.

If the transmit/receive bit is active, the McASP functions normally during that time slot; otherwise, the McASP is inactive during that time slot; no update to the buffer occurs, and no event is generated. Transmit pins are automatically set to a high-impedance state, 0, or 1 during that slot, as determined by bit DISMOD in SRCTL[n].

Figure 21-6 shows when the transmit DMA event AXEVT is generated. See Section 21.3.8.1.1 for details on data ready and the initialization period indication. The transmit DMA event for an active time slot (slot N) is generated during the previous time slot (slot N - 1), regardless if the previous time slot (slot N - 1) is active or inactive.

During an active transmit time slot (slot N), if the next time slot (slot N + 1) is configured to be active, the copy from XRBUF[n] to XRSR[n] generates the DMA event for time slot N + 1. If the next time slot (slot N + 1) is configured to be inactive, then the DMA event will be delayed to time slot M - 1. In this case, slot M is the next active time slot. The DMA event for time slot M is generated during the first bit time of slot M - 1.

The receive DMA request generation does not need this capability, since the receive DMA event is generated after data is received in the buffer (looks back in time). If a time slot is disabled, then no data is copied to the buffer for that time slot and no DMA event is generated.

Figure 21-6. Transmit DMA Event (AXEVT) Generation in TDM Time Slots

A See Section 21.3.10.2, step 7a.

Copyright © 2011, Texas Instruments Incorporated

21.3.6.2.2 Special 384 Slot TDM Mode for Connection to External DIR

The McASP receiver also supports a 384 time slot TDM mode (DIR mode), to support S/PDIF, AES-3, IEC-60958 receiver ICs whose natural block (block corresponds to McASP frame) size is 384 samples. The advantage to using the 384 time slot TDM mode is that interrupts may be generated synchronous to the S/PDIF, AES-3, IEC-60958, such as the last slot interrupt.

The receive TDM time slot register (RTDM) should be programmed to all 1s during reception of a DIR block. Other TDM functionalities (for example, inactive slots) are not supported (only the slot counter counts the 384 subframes in a block).

To receive data in the DIR mode, the following pins are typically needed:

- ACLKR - receive bit clock.
- AFSR - receive frame sync (or commonly called left/right clock). In this mode, AFSR should be connected to a DIR which outputs a start of block signal, instead of LRCLK.
- One or more serial data pins, AXRn, whose serializers have been configured to receive.

For this special DIR mode, the control registers can be configured just as for TDM mode, except set RMOD in AFSRCTL to 384 to receive 384 time slots.

21.3.6.3 Digital Audio Interface Transmit (DIT) Transfer Mode

In addition to the TDM and burst transfer modes, which are suitable for transmitting audio data between ICs inside the same system, the digital audio interface transmit (DIT) transfer mode of the McASP also supports transmission of audio data in the S/PDIF, AES-3, or IEC-60958 format. These formats are designed to carry audio data between different systems through an optical or coaxial cable. The DIT mode only applies to serializers configured as transmitters, not receivers. Refer to for a description of the S/PDIF format.

21.3.6.3.1 Transmit DIT Encoding

The McASP operation in DIT mode is basically identical to the 2 time slot TDM mode, but the data transmitted is output as a biphase mark encoded bit stream, with preamble, channel status, user data, validity, and parity automatically stuffed into the bit stream by the McASP. The McASP includes separate validity bits for even/odd subframes and two 384-bit RAM modules to hold channel status and user data bits.

The transmit TDM time slot register (XTDM) should be programmed to all 1s during DIT mode. TDM functionality is not supported in DIT mode, except that the TDM slot counter counts the DIT subframes.

To transmit data in the DIT mode, the following pins are typically needed:

- AHCLKX - transmit high-frequency master clock.
- One or more serial data pins, AXRn, whose serializers have been configured to transmit.

AHCLKX is optional (the internal clock source may be used instead), but if used as a reference, the processor provides a clock check circuit that continually monitors the AHCLKX input for stability.

If the McASP is configured to transmit in the DIT mode on more than one serial data pin, the bit streams on all pins will be synchronized. In addition, although they will carry unique audio data, they will carry the same channel status, user data, and validity information.

The actual 24-bit audio data must always be in bit positions 23-0 after passing through the first three stages of the transmit format unit.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

For left-aligned Q31 data, the following transmit format unit settings process the data into right aligned 24-bit audio data ready for transmission:

- XROT = 010 (rotate right by 8 bits).
- XRVRS = 0 (no bit reversal, LSB first).
- XMASK = FFFF FF00h-FFFF 0000h (depending upon whether 24, 23, 22, 21, 20, 19, 18, 17, or 16 valid audio data bits are present).
- XPAD = 00 (pad extra bits with 0).

For right-aligned data, the following transmit format unit settings process the data into right aligned 24-bit audio data ready for transmission:

- XROT = 000 (rotate right by 0 bits).
- XRVRS = 0 (no bit reversal, LSB first).
- XMASK = 00FF FFFFh to 0000 FFFFh (depending upon whether 24, 23, 22, 21, 20, 19, 18, 17, or 16 valid audio data bits are present).
- XPAD = 00 (pad extra bits with 0).

21.3.6.3.2 Transmit DIT Clock and Frame Sync Generation

The DIT transmitter only works in the following configuration:

- In transmit frame control register (AFSXCTL):
  - Internally-generated transmit frame sync, FSXM = 1.
  - Rising-edge frame sync, FSXP = 0.
  - Bit-width frame sync, FXWID = 0.
  - 384-slot TDM, XMOD = 1 1000 0000b.
- In transmit clock control register (ACLKXCTL), ASYNC = 1.
- In transmit bitstream format register (XFMT), XSSZ = 1111 (32-bit slot size).

All combinations of AHCLKX and ACLKX are supported.

This is a summary of the register configurations required for DIT mode. The DIT mode specific bit fields are in bold face:

- PFUNC: The data pins must be configured for McASP function. If AHCLKX is used, it must also be configured for McASP function.
- PDIR: The data pins must be configured as outputs. If AHCLKX is used as an input reference, it should be configured as input. If internal clock source AUXCLK is used as the reference clock, it may be output on the AHCLKX pin by configuring AHCLKX as an output.
- PDOUT, PDIN, PDSET, PDCLR: Not applicable for DIT operation. Leave at default.
- GBLCTL: Follow the initialization sequence in Section 21.3.10.2 to configure this register.
- AMUTE: Program all fields according to mute control desired.
- DLBCTL: Not applicable. Loopback is not supported for DIT mode. Leave at default.
- DITCTL: **DITEN** bit must be set to 1 to enable DIT mode. Configure other bits as desired.
- RMASK: Not applicable. Leave at default.
- RFMT: Not applicable. Leave at default.
- AFSRCTL: Not applicable. Leave at default.
- ACLKRCTL: Not applicable. Leave at default.
- AHCLKRCTL: Not applicable. Leave at default.
- RTDM: Not applicable. Leave at default.
- RINTCTL: Not applicable. Leave at default.
- RCLKCHK: Not applicable. Leave at default.
- **XMASK**: Mask desired bits according to the discussion in this section, depending upon left-aligned or right-aligned internal data.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

- **XFMT: XDATDLY** = 0. **XRVRS** = 0. **XPAD** = 0. **XPBIT** = default (not applicable). **XSSZ** = Fh (32-bit slot). XBUSEL = configured as desired. **XROT** bit is configured according to the discussion in this section, either 0 or 8-bit rotate.
- **AFSXCTL**: Configure the bits according to the discussion in this section.
- **ACLKXCTL**: **ASYNC** = 1. Program CLKXDIV bits to obtain the bit clock rate desired. Configure CLKXP and CLKXM bits as desired, because CLKX is not actually used in the DIT protocol.
- **AHCLKXCTL**: Program all fields according to high-frequency clock desired.
- **XTDM**: Set to FFFF FFFFh for all active slots for DIT transfers.
- XINTCTL: Program all fields according to interrupts desired.
- XCLKCHK: Program all fields according to clock checking desired.
- SRCTLn: Set **SRMOD** = 1 (transmitter) for the DIT pins. DISMOD field is don't care for DIT mode.
- **DITCSRA[n], DITCSRB[n]**: Program the channel status bits as desired.
- **DITUDRA[n], DITUDRB[n]**: Program the user data bits as desired.

21.3.6.3.3 DIT Channel Status and User Data Register Files

The channel status registers (DITCSRA*n* and DITCSRB*n*) and user data registers (DITUDRA*n* and DITUDRB*n*) are not double buffered. Typically the programmer uses one of the synchronizing interrupts, such as last slot, to create an event at a safe time so the register may be updated. In addition, the CPU reads the transmit TDM slot counter to determine which word of the register is being used.

It is a requirement that the software avoid writing to the word of user data and channel status that are being used to encode the current time slot; otherwise, it will be indeterminate whether the old or new data is used to encode the bitstream.

The DIT subframe format is defined in . The channel status information (C) and User Data (U) are defined in these DIT control registers:

- DITCSRA0 to DITCSRA5: The 192 bits in these six registers contain the channel status information for the LEFT channel within each frame.
- DITCSRB0 to DITCSRB5: The 192 bits in these six registers contain the channel status information for the RIGHT channel within each frame.
- DITUDRA0 to DITUDRA5: The 192 bits in these six registers contain the user data information for the LEFT channel within each frame.
- DITUDRB0 to DITUDRB5: The 192 bits in these six registers contain the user data information for the RIGHT channel within each frame.

The S/PDIF block format is shown in . There are 192 frames within a block (frame 0 to frame 191). Within each frame there are two subframes (subframe 1 and 2 for left and right channels, respectively). The channel status and user data information sent on each subframe is summarized in Table 21-5.

21.3.7 General Architecture

21.3.7.1 Serializers

Figure 21-7 shows the block diagram of the serializer and its interface to other units within the McASP. The serializers take care of shifting serial data in and out of the McASP. Each serializer consists of a shift register (XRSR), a data buffer (XRBUF), a control register (SRCTL), and logic to support the data alignment options of the McASP. For each serializer, there is a dedicated serial data pin (AXRn) and a dedicated control register (SRCTL[n]). The control register allows the serializer to be configured as a transmitter, receiver, or as inactive. When configured as a transmitter the serializer shifts out data to the serial data pin AXRn. When configured as a receiver, the serializer shifts in data from the AXRn pin. The serializer is clocked from the transmit/receive section clock (ACLKX/ACLKR) if configured to transmit/receive respectively.

All serializers that are configured to transmit operate in lock-step. Similarly, all serializers that are configured to receive also operate in lock-step. This means that at most there are two zones per McASP, one for transmit and one for receive.

Figure 21-7. Individual Serializer and Connections Within McASP

For receive, data is shifted in through the AXRn pin to the shift register XRSR. Once the entire slot of data is collected in the XRSR, the data is copied to the data buffer XRBUF. The data is now ready to be read by the processor through the RBUF register, which is an alias of the XRBUF for receive. When the processor reads from the RBUF, the McASP passes the data from RBUF through the receive format unit and returns the formatted data to the processor.

For transmit, the processor services the McASP by writing data into the XBUF register, which is an alias of the XRBUF for transmit. The data automatically passes through the transmit format unit before actually reaching the XRBUF register in the serializer. The data is then copied from XRBUF to XRSR, and shifted out from the AXRn synchronously to the serial clock.

In DIT mode, in addition to the data, the serializer shifts out other DIT-specific information accordingly (preamble, user data, etc.).

The serializer configuration is controlled by SRCTL[n].

21.3.7.2 Format Unit

The McASP has two data formatting units, one for transmit and one for receive. These units automatically remap the data bits within the transmitted and received words between a natural format for the processor (such as a Q31 representation) and the required format for the external serial device (such as "I2S format"). During the remapping process, the format unit also can mask off certain bits or perform sign extension.

Since all transmitters share the same data formatting unit, the McASP only supports one transmit format at a time. For example, the McASP will not transmit in "I2S format" on serializer 0, while transmitting "Left Justified" on serializer 1. Likewise, the receiver section of the McASP only supports one data format at a time, and this format applies to all receiving serializers. However, the McASP can transmit in one format while receiving in a completely different format.

Copyright © 2011, Texas Instruments Incorporated

This formatting unit consists of three stages:

- Bit mask and pad (masks off bits, performs sign extension)
- Rotate right (aligns data within word)
- Bit reversal (selects between MSB first or LSB first)

Figure 21-8 shows a block diagram of the receive formatting unit, and Figure 21-9 shows the transmit formatting unit. Note that the order in which data flows through the three stages is different between the transmit and receive formatting units.

Figure 21-8. Receive Format Unit

Figure 21-9. Transmit Format Unit

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

The bit mask and pad stage includes a full 32-bit mask register, allowing selected individual bits to either pass through the stage unchanged, or be masked off. The bit mask and pad then pad the value of the masked off bits by inserting either a 0, a 1, or one of the original 32 bits as the pad value. The last option allows for sign-extension when the sign bit is selected to pad the remaining bits.

The rotate right stage performs bitwise rotation by a multiple of 4 bits (between 0 and 28 bits), programmable by the (R/X)FMT register. Note that this is a rotation process, not a shifting process, so bit 0 gets shifted back into bit 31 during the rotation.

The bit reversal stage either passes all 32 bits directly through, or swaps them. This allows for either MSB or LSB first data formats. If bit reversal is not enabled, then the McASP will naturally transmit and receive in an LSB first order.

Finally, note that the (R/X)DATDLY bits in (R/X)FMT also determine the data format. For example, the difference between I2S format and left-justified is determined by the delay between the frame sync edge and the first data bit of a given time slot. For I2S format, (R/X)DATDLY should be set to a 1-bit delay, whereas for left-justified format, it should be set to a 0-bit delay.

The combination of all the options in (R/X)FMT means that the McASP supports a wide variety of data formats, both on the serial data lines, and in the internal processor representation.

Section 21.3.8.3 provides more detail and specific examples. The examples use internal representation in integer and Q31 notation, but other fractional notations are also possible.

21.3.7.3 State Machine

The receive and transmit sections have independent state machines. Each state machine controls the interactions between the various units in the respective section. In addition, the state machine keeps track of error conditions and serial port status.

No serial transfers can occur until the respective state machine is released from reset. See initialization sequence for details (Section 21.3.10).

The receive state machine is controlled by the RFMT register, and it reports the McASP status and error conditions in the RSTAT register. Similarly, the transmit state machine is controlled by the XFMT register, and it reports the McASP status and error conditions in the XSTAT register.

21.3.7.4 TDM Sequencer

There are separate TDM sequencers for the transmit section and the receive section. Each TDM sequencer keeps track of the slot count. In addition, the TDM sequencer checks the bits of (R/X)TDM and determines if the McASP should receive/transmit in that time slot.

If the McASP should participate (transmit/receive bit is active) in the time slot, the McASP functions normally. If the McASP should not participate (transmit/receive bit is inactive) in the time slot, no transfers between the XRBUF and XRSR registers in the serializer would occur during that time slot. In addition, the serializers programmed as transmitters place their data output pins in a predetermined state (logic low, high, or high impedance) as programmed by each serializer control register (SRCTL). Refer also to Section 21.3.6.2 for details on how DMA event or interrupt generations are handled during inactive time slots in TDM mode.

The receive TDM sequencer is controlled by register RTDM and reports current receive slot to RSLOT. The transmit TDM sequencer is controlled by register XTDM and reports current transmit slot to XSLOT.

21.3.7.5 Clock Check Circuit

A common source of error in audio systems is a serial clock failure due to instabilities in the off-chip DIR circuit. To detect a clock error quickly, a clock-check circuit is included in the McASP for both transmit and receive clocks, since both may be sourced from off chip.

The clock check circuit can detect and recover from transmit and receive clock failures. See Section 21.3.8.4.6 for implementation and programming details.

21.3.7.6 Pin Function Control

All McASP pins except AMUTEIN are bidirectional input/output pins. In addition, these bidirectional pins function either as McASP or general-purpose I/O (GPIO) pins. The following registers control the pin functions:

- Pin function register (PFUNC): selects pin to function as McASP or GPIO.
- Pin direction register (PDIR): selects pin to be input or output.
- Pin data input register (PDIN): shows data input at the pin.
- Pin data output register (PDOUT): data to be output at the pin if the pin is configured as GPIO output (PFUNC[n] = 1 and PDIR[n] = 1). Not applicable when the pin is configured as McASP pin (PFUNC[n] = 0).
- Pin data set register (PDSET): alias of PDOUT. Writing a 1 to PDSET[n] sets the respective PDOUT[n] to 1. Writing a 0 has no effect. Applicable only when the pin is configured as GPIO output (PFUNC[n] = 1 and PDIR[n] = 1).
- Pin data clear register (PDCLR): alias of PDOUT. Writing a 1 to PDCLR[n] clears the respective PDOUT[n] to 0. Writing a 0 has no effect. Applicable only when the pin is configured as GPIO output (PFUNC[n] = 1 and PDIR[n] = 1).

See the register descriptions in Section 21.4 for details on the mapping of each McASP pin to the register bits. Figure 21-10 shows the pin control block diagram.

Figure 21-10. McASP I/O Pin Control Block Diagram

21.3.7.6.1 McASP Pin Control-Transmit and Receive

You must correctly set the McASP GPIO registers PFUNC and PDIR, even when McASP pins are used for their serial port (non-GPIO) function.

Serial port functions include:

- Clock pins (ACLKX, ACLKR, AHCLKX, AHCLKR, AFSX, AFSR) used as clock inputs and outputs.
- Serializer data pins (AXRn) used to transmit or receive.
- AMUTE used as a mute output signal.

When using these pins in their serial port function, you must clear PFUNC[n] to 0 for each pin.

Also, certain outputs require PDIR[n] = 1, such as clock pins used as clock outputs, serializer data pins used to transmit, and AMUTE used as mute output.

Clock inputs and serializers configured to receive must have PDIR[n] = 0.

PFUNC and PDIR do not control the AMUTEIN signal, it is usually tied to a device level interrupt pin (consult device datasheet). If used as a mute input, this pin needs to be configured as an input in the appropriate peripheral.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Finally, there is an important advantage to having separate control of pin direction (by PDIR), and the choice of internal versus external clocking (by CLKRM/CLKXM). Depending on the specific device and usage, you might select an external clock (CLKRM = 0), while enabling the internal clock divider, and the clock pin as an output in the PDIR register (PDIR[ACLKR] = 1). In this case, the bit clock is an output (PDIR[ACLKR] = 1) and, therefore, routed to the ACLKR pin. However, because CLKRM = 0, the bit clock is then routed back to the McASP module as an "external" clock source. This may result in less skew between the clock inside the McASP and the clock in the external device, thus producing more balanced setup and hold times for a particular system. As a result, this may allow a higher serial clock rate interface.

21.3.8 Operation

This section discusses the operation of the McASP.

21.3.8.1 Data Transmission and Reception

The processor services the McASP by writing data to the XBUF register(s) for transmit operations, and by reading data from the RBUF register(s) for receive operations. The McASP sets status flag and notifies the processor whenever data is ready to be serviced. Section 21.3.8.1.1 discusses data ready status in detail.

The XBUF and RBUF registers can be accessed through one of the two peripheral ports of the device:

- The data port (DAT): This port is dedicated for data transfers on the device.
- The configuration bus (CFG): This port is used for both data transfers and peripheral configuration control on the device.

Section 21.3.8.1.2 and Section 21.3.8.1.3 discuss how to perform transfers through the data port and the configuration bus.

Either the CPU or the DMA can be used to service the McASP through any of these two peripheral ports. The CPU and DMA usages are discussed in Section 21.3.8.1.4 and Section 21.3.12.2.

21.3.8.1.1 Data Ready Status and Event/Interrupt Generation

21.3.8.1.1.1 Transmit Data Ready

The transmit data ready flag XDATA bit in the XSTAT register reflects the status of the XBUF register. The XDATA flag is set when data is transferred from the XRBUF[n] buffers to the XRSR[n] shift registers, indicating that the XBUF is empty and ready to accept new data from the processor. This flag is cleared when the XDATA bit is written with a 1, or when all the serializers configured as transmitters are written by the processor.

Whenever XDATA is set, an DMA event AXEVT is automatically generated to notify the DMA of the XBUF empty status. An interrupt AXINT is also generated if XDATA interrupt is enabled in the XINTCTL register (See Section 21.3.11.2 for details).

For DMA requests, the McASP does not require XSTAT to be read between DMA events. This means that even if XSTAT already has the XDATA flag set to 1 from a previous request, the next transfer triggers another DMA request.

Since all serializers act in lockstep, only one DMA event is generated to indicate that all active transmit serializers are ready to be written to with new data.

Figure 21-11 shows the timing details of when AXEVT is generated at the McASP boundary. In this example, as soon as the last bit (bit A0) of Word A is transmitted, the McASP sets the XDATA flag and generates an AXEVT event. However, it takes up to 5 McASP system clocks (AXEVT Latency) before AXEVT is active at the McASP boundary. Upon AXEVT, the processor can begin servicing the McASP by writing Word C into the XBUF (Processor Service Time). The processor must write Word C into the XBUF no later than the setup time required by the McASP (Setup Time).

The maximum Processor Service Time (Figure 21-11) can be calculated as:

Processor Service Time = Time Slot - AXEVT Latency - Setup Time

Copyright © 2011, Texas Instruments Incorporated

Figure 21-11. Processor Service Time Upon Transmit DMA Event (AXEVT)

A Refer to the device-specific data manual for the McASP system clock source. This is not the same as AUXCLK.

Example 21-1. Processor Service Time Calculation for Transmit DMA Event (AXEVT)

The following is an example to show how to calculate Processor Service Time. Assume the following setup:

- Device: C64x+ DSP at 300 MHz.
- McASP transmits in I2S format at 192 kHz frame rate. Assume slot size is 32 bit.

With the above setup, we obtain the following parameters corresponding to Figure 21-11:

- Calculation of McASP system clock cycle:
  - C64x+ DSP uses SYSCLK2 as the McASP system clock. It runs at 150 MHz (half of device frequency).
  - Therefore, McASP system clock cycle = 1/150 MHz = 6.7 ns.
- Calculation of ACLKX clock cycle:
  - This example has two 32-bit slots per frame, for a total of 64 bits per frame.
  - ACLKX clock cycle is (1/192 kHz)/64 = 81.4 ns.
- Time Slot between AXEVT events:
  - For I2S format, McASP generates two AXEVT events per 192 kHz frame.
  - Therefore, Time Slot between AXEVT events is (1/192 kHz)/2 = 2604 ns.
- AXEVT Latency:
  = 5 McASP system clocks
  = 6.7 ns × 5 = 33.5 ns
- Setup Time
  = 3 McASP system clocks + 4 ACLKX cycles
  = (6.7 ns × 3) + (81.4 ns × 4)
  = 345.7 ns
- Processor Service Time
  = Time Slot - AXEVT Latency - Setup Time
  = 2604 ns - 33.5 ns - 345.7 ns
  = 2225 ns

21.3.8.1.1.2 Receive Data Ready

Similarly, the receive data ready flag RDATA bit in the RSTAT reflects the status of the RBUF register. The RDATA flag is set when data is transferred from the XRSR[n] shift registers to the XRBUF[n] buffers, indicating that the RBUF contains received data and is ready to have the processor read the data. This flag is cleared when the RDATA bit is written with a 1, or when all the serializers configured as receivers are read.

Whenever RDATA is set, an DMA event AREVT is automatically generated to notify the DMA of the RBUF ready status. An interrupt ARINT is also generated if RDATA interrupt is enabled in the RINTCTL register (See Section 21.3.11.3 for details).

For DMA requests, the McASP does not require RSTAT to be read between DMA events. This means that even if RSTAT already has the RDATA flag set to 1 from a previous request, the next transfer triggers another DMA request.

Since all serializers act in lockstep, only one DMA event is generated to indicate that all active receive serializers are ready to receive new data.

Figure 21-12 shows the timing details of when AREVT is generated at the McASP boundary. In this example, as soon as the last bit (bit A0) of Word A is received, the McASP sets the RDATA flag and generates an AREVT event. However, it takes up to 5 McASP system clocks (AREVT Latency) before AREVT is active at the McASP boundary. Upon AREVT, the processor can begin servicing the McASP by reading Word A from the RBUF (Processor Service Time). The processor must read Word A from the XBUF no later than the setup time required by the McASP (Setup Time).

The maximum Processor Service Time (Figure 21-12) can be calculated as:

Processor Service Time = Time Slot - AREVT Latency - Setup Time

The Processor Service Time calculation for receive is similar to the calculation for transmit. See Example 21-1 for Processor Service Time calculation using transmit as an example.

Figure 21-12. Processor Service Time Upon Receive DMA Event (AREVT)

A The device uses SYSCLK2 as the McASP system clock source.

21.3.8.1.2 Transfers Through the Data Port (DAT)

NOTE: To perform internal transfers through the data port, clear XBUSEL/RBUSEL bit to 0 in the respective XFMT/RFMT registers. Failure to do so will result in software malfunction.

Typically, you will access the McASP XRBUF registers through the data port. To access through the data port, simply have the CPU or DMA access the XRBUF through its data port location. Refer to the device-specific data manual for the exact memory address. Through the data port, the DMA/CPU can service all the serializers through a single address. The McASP automatically cycles through the appropriate serializers.

For transmit operations through the data port, the DMA/CPU should write to the same XBUF data port address to service all of the active transmit serializers. In addition, the DMA/CPU should write to the XBUF for all active transmit serializers in incremental (although not necessarily consecutive) order. For example, if serializers 0, 4, and 5, are set up as active transmitters, the DMA/CPU should write to the XBUF data port address four times with data for serializers 0, 4, and 5, upon each transmit data ready event. This exact servicing order must be followed so that data appears in the appropriate serializers.

Similarly, for receive operations through the data port, the DMA/CPU should read from the same RBUF data port address to service all of the active receive serializers. In addition, reads from the active receive serializers through the data port return data in incremental (although not necessarily consecutive) order. For example, if serializers 1, 2, and 3, are set up as active receivers, the DMA/CPU should read from the RBUF data port address four times to obtain data for serializers 1, 2, and 3, in this exact order, upon each receive data ready event.

When transmitting, the DMA/CPU must write data to each serializer configured as "active" and "transmit" within each time slot. Failure to do so results in a buffer underrun condition (Section 21.3.8.4.2). Similarly, when receiving, data must be read from each serializer configured as "active" and "receive" within each time slot. Failure to do results in a buffer overrun condition (Section 21.3.8.4.3).

To perform internal transfers through the data port, clear XBUSEL/RBUSEL bit to 0 in the respective XFMT/RFMT registers.

21.3.8.1.3 Transfers Through the Configuration Bus (CFG)

NOTE: To perform internal transfers through the configuration bus, set XBUSEL/RBUSEL bit to 1 in the respective XFMT/RFMT registers. Failure to do so will result in software malfunction.

In this method, the DMA/CPU accesses the XRBUF registers through the configuration bus address. The exact XRBUF register address for any particular serializer is determined by adding the offset for that particular serializer to the base address for the particular McASP (found in the device-specific data manual). XRBUF for the serializers configured as transmitters is given the name XBUF*n*. For example, the XRBUF associated with transmit serializer 2 is named XBUF2. Similarly, XRBUF for the serializers configured as receivers is given the name RBUF*n*.

Accessing the XRBUF registers through the data port is different because the CPU/DMA only needs to access one single address. When accessing through the configuration bus, the CPU/DMA must provide the exact XBUF*n* or RBUF*n* address for each access.

When transmitting, DMA/CPU must write data to each serializer configured as "active" and "transmit" within each time slot. Failure to do so results in a buffer underrun condition (Section 21.3.8.4.2). Similarly when receiving, data must be read from each serializer configured as "active" and "receive" within each time slot. Failure to do results in a buffer overrun condition (Section 21.3.8.4.3).

To perform internal transfers through the configuration bus, set XBUSEL/RBUSEL bit to 1 in the respective XFMT/RFMT registers.

21.3.8.1.4 Using the CPU for McASP Servicing

The CPU can be used to service the McASP through interrupt (upon AXINT/ARINT interrupts) or through polling the XDATA bit in the XSTAT register. As discussed in Section 21.3.8.1.2 and Section 21.3.8.1.3, the CPU can access through either the data port or through the configuration bus.

Copyright © 2011, Texas Instruments Incorporated

To use the CPU to service the McASP through interrupts, the XDATA/RDATA bit must be enabled in the respective XINTCTL/RINTCTL registers, to generate interrupts AXINT/ARINT to the CPU upon data ready.

21.3.8.2 McASP Audio FIFO (AFIFO)

The AFIFO contains two FIFOs: one Read FIFO (RFIFO), and one Write FIFO (WFIFO). To ensure backward compatibility with existing software, both the Read and Write FIFOs are disabled by default. See Figure 21-13 for a high-level block diagram of the AFIFO.

The AFIFO may be enabled/disabled and configured via the WFIFOCTL and RFIFOCTL registers. Note that if the Read or Write FIFO is to be enabled, it must be enabled prior to initializing the receive/transmit section of the McASP (see Section 21.3.10.2 for details).

Figure 21-13. McASP Audio FIFO (AFIFO) Block Diagram

21.3.8.2.1 AFIFO Data Transmission

When the Write FIFO is disabled, transmit DMA requests pass through directly from the McASP to the host/DMA controller. Whether the WFIFO is enabled or disabled, the McASP generates transmit DMA requests as needed; the AFIFO is “invisible” to the McASP.

When the Write FIFO is enabled, transmit DMA requests from the McASP are sent to the AFIFO, which in turn generates transmit DMA requests to the host/DMA controller.

If the Write FIFO is enabled, upon a transmit DMA request from the McASP, the WFIFO writes *WNUMDMA* 32-bit words to the McASP if and when there are at least *WNUMDMA* words in the Write FIFO. If there are not, the WFIFO waits until this condition has been satisfied. At that point, it writes *WNUMDMA* words to the McASP. (See description for WFIFOCTL.WNUMDMA in Section 21.4.43.)

If the host CPU writes to the Write FIFO, independent of a transmit DMA request, the WFIFO will accept host writes until full. After this point, excess data will be discarded.

Note that when the WFIFO is first enabled, it will immediately issue a transmit DMA request to the host. This is because it begins in an empty state, and is therefore ready to accept data.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

21.3.8.2.1.1 Transmit DMA Event Pacer

The AFIFO may be configured to delay making a transmit DMA request to the host until the Write FIFO has enough space for a specified number of words. In this situation, the number of transmit DMA requests to the host or DMA controller is reduced.

If the Write FIFO has space to accept *WNUMEVT* 32-bit words, it generates a transmit DMA request to the host and then waits for a response. Once *WNUMEVT* words have been written to the FIFO, it checks again to see if there is space for *WNUMEVT* 32-bit words. If there is space, it generates another transmit DMA request to the host, and so on. In this fashion, the Write FIFO will attempt to stay filled.

Note that if transmit DMA event pacing is desired, WFIFOCTL.WNUMEVT should be set to a non-zero integer multiple of the value in WFIFOCTL.WNUMDMA. If transmit DMA event pacing is not desired, then the value in WFIFOCTL.WNUMEVT should be set equal to the value in WFIFOCTL.WNUMDMA.

21.3.8.2.2 AFIFO Data Reception

When the Read FIFO is disabled, receive DMA requests pass through directly from McASP to the host/DMA controller. Whether the RFIFO is enabled or disabled, the McASP generates receive DMA requests as needed; the AFIFO is “invisible” to the McASP.

When the Read FIFO is enabled, receive DMA requests from the McASP are sent to the AFIFO, which in turn generates receive DMA requests to the host/DMA controller.

If the Read FIFO is enabled and the McASP makes a receive DMA request, the RFIFO reads *RNUMDMA* 32-bit words from the McASP, if and when the RFIFO has space for *RNUMDMA* words. If it does not, the RFIFO waits until this condition has been satisfied; at that point, it reads *RNUMDMA* words from the McASP. (See description for RFIFOCTL.RNUMDMA in Section 21.4.45.)

If the host CPU reads the Read FIFO, independent of a receive DMA request, and the RFIFO at that time contains less than *RNUMEVT* words, those words will be read correctly, emptying the FIFO.

21.3.8.2.2.1 Receive DMA Event Pacer

The AFIFO may be configured to delay making a receive DMA request to the host until the Read FIFO contains a specified number of words. In this situation, the number of receive DMA requests to the host or DMA controller is reduced.

If the Read FIFO contains at least *RNUMEVT* 32-bit words, it generates a receive DMA request to the host and then waits for a response. Once *RNUMEVT* 32-bit words have been read from the RFIFO, the RFIFO checks again to see if it contains at least another *RNUMEVT* words. If it does, it generates another receive DMA request to the host, and so on. In this fashion, the Read FIFO will attempt to stay empty.

Note that if receive DMA event pacing is desired, RFIFOCTL.RNUMEVT should be set to a non-zero integer multiple of the value in RFIFOCTL.RNUMDMA. If receive DMA event pacing is not desired, then the value in RFIFOCTL.RNUMEVT should be set equal to the value in RFIFOCTL.RNUMDMA.

21.3.8.2.3 Arbitration Between Transmit and Receive DMA Requests

If both the WFIFO and the RFIFO are enabled and a transmit DMA request and receive DMA request occur simultaneously, priority is given to the transmit DMA request. Once a transfer is in progress, it is allowed to complete.

If only the WFIFO is enabled and a transmit DMA request and receive DMA request occur simultaneously, priority is given to the transmit DMA request. Once a transfer is in progress, it is allowed to complete.

If only the RFIFO is enabled and a transmit DMA request and receive DMA request occur simultaneously, priority is given to the receive DMA request. Once a transfer is in progress, it is allowed to complete.

21.3.8.3 Formatter

21.3.8.3.1 Transmit Bit Stream Data Alignment

The McASP transmitter supports serial formats of:

- Slot (or Time slot) size = 8, 12, 16, 20, 24, 28, 32 bits.
- Word size ≤ Slot size.
- Alignment: when more bits/slot than bits/words, then:
  - Left aligned = word shifted first, remaining bits are pad.
  - Right aligned = pad bits are shifted first, word occupies the last bits in slot.
- Order: order of bits shifted out:
  - MSB: most-significant bit of word is shifted out first, last bit is LSB.
  - LSB: least-significant bit of word is shifted out last, last bit is MSB.

Hardware support for these serial formats comes from the programmable options in the transmit bitstream format register (XFMT):

- XRVRS: bit reverse (1) or no bit reverse (0).
- XROT: rotate right by 0, 4, 8, 12, 16, 20, 24, or 28 bits.
- XSSZ: transmit slot size of 8, 12, 16, 20, 24, 28, or 32 bits.

XSSZ should always be programmed to match the slot size of the serial stream. The word size is not directly programmed into the McASP, but rather is used to determine the rotation needed in the XROT field.

Table 21-6 and Figure 21-14 show the XRVRS and XROT fields for each serial format and for both integer and Q31 fractional internal representations.

This discussion assumes that all slot size (SLOT in Table 21-6) and word size (WORD in Table 21-6) options are multiples of 4, since the transmit rotate right unit only supports rotation by multiples of 4. However, the bit mask/pad unit does allow for any number of significant digits. For example, a Q31 number may have 19 significant digits (word) and be transmitted in a 24-bit slot; this would be formatted as a word size of 20 bits and a slot size of 24 bits. However, it is possible to set the bit mask unit to only pass the 19 most-significant digits (program the mask value to FFFF E000h). The digits that are not significant can be set to a selected pad value, which can be any one of the significant digits, a fixed value of 0, or a fixed value of 1.

The transmit bit mask/pad unit operates on data as an initial step of the transmit format unit (see Figure 21-9), and the data is aligned in the same representation as it is written to the transmitter by the processor (typically Q31 or integer).

Table 21-6. Transmit Bitstream Data Alignment

Figure 21-14	Bit Stream Order	Bit Stream Alignment	Internal Numeric Representation	XFMT Bit	
				XROT [1]	XRVRS
(a) [2]	MSB first	Left aligned	Q31 fraction	0	1
(b)	MSB first	Right aligned	Q31 fraction	SLOT - WORD	1
(c)	LSB first	Left aligned	Q31 fraction	32 - WORD	0
(d)	LSB first	Right aligned	Q31 fraction	32 - SLOT	0
(e) [2]	MSB first	Left aligned	Integer	WORD	1
(f)	MSB first	Right aligned	Integer	SLOT	1
(g)	LSB first	Left aligned	Integer	0	0
(h)	LSB first	Right aligned	Integer	(32 - (SLOT - WORD)) % 32	0

(1) WORD = Word size rounded up to the nearest multiple of 4; SLOT = slot size; % = modulo operator
(2) To transmit in I2S format, use MSB first, left aligned, and also select XDATDLY = 01 (1 bit delay)

21.3.8.3.2 Receive Bit Stream Data Alignment

The McASP receiver supports serial formats of:

- Slot or time slot size = 8, 12, 16, 20, 24, 28, 32 bits.
- Word size ≤ Slot size.
- Alignment when more bits/slot than bits/words, then:
  - Left aligned = word shifted first, remaining bits are pad.
  - Right aligned = pad bits are shifted first, word occupies the last bits in slot.
- Order of bits shifted out:
  - MSB: most-significant bit of word is shifted out first, last bit is LSB.
  - LSB: least-significant bit of word is shifted out last, last bit is MSB.

Hardware support for these serial formats comes from the programmable options in the receive bitstream format register (RFMT):

- RRVRS: bit reverse (1) or no bit reverse (0).
- RROT: rotate right by 0, 4, 8, 12, 16, 20, 24, or 28 bits.
- RSSZ: receive slot size of 8, 12, 16, 20, 24, 28, or 32 bits.

RSSZ should always be programmed to match the slot size of the serial stream. The word size is not directly programmed into the McASP, but rather is used to determine the rotation needed in the RROT field.

Table 21-7 and Figure 21-15 show the RRVRS and RROT fields for each serial format and for both integer and Q31 fractional internal representations.

This discussion assumes that all slot size and word size options are multiples of 4; since the receive rotate right unit only supports rotation by multiples of 4. However, the bit mask/pad unit does allow for any number of significant digits. For example, a Q31 number may have 19 significant digits (word) and be transmitted in a 24-bit slot; this would be formatted as a word size of 20 bits and a slot size of 24 bits. However, it is possible to set the bit mask unit to only pass the 19 most-significant digits (program the mask value to FFFF E000h). The digits that are not significant can be set to a selected pad value, which can be any one of the significant digits, a fixed value of 0, or a fixed value of 1.

The receive bit mask/pad unit operates on data as the final step of the receive format unit (see Figure 21-8), and the data is aligned in the same representation as it is read from the receiver by the processor (typically Q31 or integer).

Table 21-7. Receive Bitstream Data Alignment

Figure 21-15	Bit Stream Order	Bit Stream Alignment	Internal Numeric Representation	RFMT Bit	
				RROT [1]	RRVRS
(a) [2]	MSB first	Left aligned	Q31 fraction	SLOT	1
(b)	MSB first	Right aligned	Q31 fraction	WORD	1
(c)	LSB first	Left aligned	Q31 fraction	(32 - (SLOT - WORD)) % 32	0
(d)	LSB first	Right aligned	Q31 fraction	0	0
(e) [2]	MSB first	Left aligned	Integer	SLOT - WORD	1
(f)	MSB first	Right aligned	Integer	0	1
(g)	LSB first	Left aligned	Integer	32 - SLOT	0
(h)	LSB first	Right aligned	Integer	32 - WORD	0

(1) WORD = Word size rounded up to the nearest multiple of 4; SLOT = slot size; % = modulo operator
(2) To transmit in I2S format, select MSB first, left aligned, and also select RDATDLY = 01 (1 bit delay)

21.3.8.4 Error Handling and Management

To support the design of a robust audio system, the McASP includes error-checking capability for the serial protocol, data underrun, and data overrun. In addition, the McASP includes a timer that continually measures the high-frequency master clock every 32 AHCLKX/AHCLKR clock cycles. The timer value can be read to get a measurement of the clock frequency and has a minimum and maximum range setting that can set an error flag if the master clock goes out of a specified range.

Upon the detection of any one or more errors (software selectable), or the assertion of the AMUTEIN input pin, the AMUTE output pin may be asserted to a high or low level to immediately mute the audio output. In addition, an interrupt may be generated if desired, based on any one or more of the error sources.

21.3.8.4.1 Unexpected Frame Sync Error

An unexpected frame sync occurs when:

- In burst mode, when the next active edge of the frame sync occurs early such that the current slot will not be completed by the time the next slot is scheduled to begin.
- In TDM mode, a further constraint is that the frame sync must occur exactly during the correct bit clock (not a cycle earlier or later) and only before slot 0. An unexpected frame sync occurs if this condition is not met.

When an unexpected frame sync occurs, there are two possible actions depending upon when the unexpected frame sync occurs:

1. Early: An early unexpected frame sync occurs when the McASP is in the process of completing the current frame and a new frame sync is detected (not including overlap that occurs due to a 1 or 2 bit frame sync delay). When an early unexpected frame sync occurs:
   - Error interrupt flag is set (XSYNCERR, if an unexpected transmit frame sync occurs; RSYNCERR, if an unexpected receive frame sync occurs).
   - Current frame is not resynchronized. The number of bits in the current frame is completed. The next frame sync, which occurs after the current frame is completed, will be resynchronized.
2. Late: A late unexpected frame sync occurs when there is a gap or delay between the last bit of the previous frame and the first bit of the next frame. When a late unexpected frame sync occurs (as soon as the gap is detected):
   - Error interrupt flag is set (XSYNCERR, if an unexpected transmit frame sync occurs; RSYNCERR, if an unexpected receive frame sync occurs).
   - Resynchronization occurs upon the arrival of the next frame sync.

Late frame sync is detected the same way in both burst mode and TDM mode; however, in burst mode, late frame sync is not meaningful and its interrupt enable should not be set.

21.3.8.4.2 Buffer Underrun Error - Transmitter

A buffer underrun can only occur for serializers programmed to be transmitters. A buffer underrun occurs when the serializer is instructed by the transmit state machine to transfer data from XRBUF[n] to XRSR[n], but XRBUF[n] has not yet been written with new data since the last time the transfer occurred. When this occurs, the transmit state machine sets the XUNDRN flag.

An underrun is checked only once per time slot. The XUNDRN flag is set when an underrun condition occurs. Once set, the XUNDRN flag remains set until the processor explicitly writes a 1 to the XUNDRN bit to clear the XUNDRN bit.

In DIT mode, a pair of BMC zeros is shifted out when an underrun occurs (four bit times at 128 × fs). By shifting out a pair of zeros, a clock may be recovered on the receiver. To recover, reset the McASP and start again with the proper initialization.

In TDM mode, during an underrun case, a long stream of zeros are shifted out causing the DACs to mute. To recover, reset the McASP and start again with the proper initialization.

Copyright © 2011, Texas Instruments Incorporated

21.3.8.4.3 Buffer Overrun Error - Receiver

A buffer overrun can only occur for serializers programmed to be receivers. A buffer overrun occurs when the serializer is instructed to transfer data from XRSR[n] to XRBUF[n], but XRBUF[n] has not yet been read by either the DMA or the processor. When this occurs, the receiver state machine sets the ROVRN flag. However, the individual serializer writes over the data in the XRBUF[n] register (destroying the previous sample) and continues shifting.

An overrun is checked only once per time slot. The ROVRN flag is set when an overrun condition occurs. It is possible that an overrun occurs on one time slot but then the processor catches up and does not cause an overrun on the following time slots. However, once the ROVRN flag is set, it remains set until the processor explicitly writes a 1 to the ROVRN bit to clear the ROVRN bit.

21.3.8.4.4 DMA Error - Transmitter

A transmit DMA error, as indicated by the XDMAERR flag in the XSTAT register, occurs when the DMA (or CPU) writes more words to the DAT port of the McASP than it should. For each DMA event, the DMA should write exactly as many words as there are serializers enabled as transmitters.

XDMAERR indicates that the DMA (or CPU) wrote too many words to the McASP for a given transmit DMA event. Writing too few words results in a transmit underrun error setting XUNDRN in XSTAT.

While XDMAERR occurs infrequently, an occurrence indicates a serious loss of synchronization between the McASP and the DMA or CPU. You should reinitialize both the McASP transmitter and the DMA to resynchronize them.

21.3.8.4.5 DMA Error - Receiver

A receive DMA error, as indicated by the RDMAERR flag in the RSTAT register, occurs when the DMA (or CPU) reads more words from the DAT port of the McASP than it should. For each DMA event, the DMA should read exactly as many words as there are serializers enabled as receivers.

RDMAERR indicates that the DMA (or CPU) read too many words from the McASP for a given receive DMA event. Reading too few words results in a receiver overrun error setting ROVRN in RSTAT.

While RDMAERR occurs infrequently, an occurrence indicates a serious loss of synchronization between the McASP and the DMA or CPU. You should reinitialize both the McASP receiver and the DMA to resynchronize them.

21.3.8.4.6 Clock Failure Detection

21.3.8.4.6.1 Clock-Failure Check Startup

It is expected, initially, that the clock-failure circuits will generate an error until at least one measurement has been taken. Therefore, the clock failure interrupts, clock switch, and mute functions should not immediately be enabled, but be enabled only after a specific startup procedure. The startup procedure is:

1. For the transmit clock failure check:
   (a) Configure transmit clock failure detect logic (XMIN, XMAX, XPS) in the transmit clock check control register (XCLKCHK).
   (b) Clear transmit clock failure flag (XCKFAIL) in the transmit status register (XSTAT).
   (c) Wait until first measurement is taken (> 32 AHCLKX clock periods).
   (d) Verify no clock failure is detected.
   (e) Repeat steps b–d until clock is running and is no longer issuing clock failure errors.
   (f) After the transmit clock is measured and falls within the acceptable range, the following may be enabled:
      (i) transmit clock failure interrupt enable bit (XCKFAIL) in the transmitter interrupt control register (XINTCTL).
      (ii) transmit clock failure detect autoswitch enable bit (XCKFAILSW) in the transmit clock check control register (XCLKCHK).
      (iii) mute option (XCKFAIL) in the mute control register (AMUTE).
2. For the receive clock failure check:
   (a) Configure receive clock failure detect logic (RMIN, RMAX, RPS) in the receive clock check control register (RCLKCHK).
   (b) Clear receive clock failure flag (RCKFAIL) in the receive status register (RSTAT).
   (c) Wait until first measurement is taken (> 32 AHCLKR clock periods).
   (d) Verify no clock failure is detected.
   (e) Repeat steps b–d until clock is running and is no longer issuing clock failure errors.
   (f) After the receive clock is measured and falls within the acceptable range, the following may be enabled:
      (i) receive clock failure interrupt enable bit (RCKFAIL) in the receiver interrupt control register (RINTCTL).
      (ii) mute option (RCKFAIL) in the mute control register (AMUTE).

21.3.8.4.6.2 Transmit Clock Failure Check and Recovery

The transmit clock failure check circuit (Figure 21-16) works off both the internal McASP system clock and the external high-frequency serial clock (AHCLKX). It continually counts the number of system clocks for every 32 high rate serial clock (AHCLKX) periods, and stores the count in XCNT of the transmit clock check control register (XCLKCHK) every 32 high rate serial clock cycles.

The logic compares the count against a user-defined minimum allowable boundary (XMIN), and automatically flags an interrupt (XCKFAIL in XSTST) when an out-of-range condition occurs. An out-of-range minimum condition occurs when the count is smaller than XMIN. The logic continually compares the current count (from the running system clock counter) against the maximum allowable boundary (XMAX). This is in case the external clock completely stops, so that the counter value is not copied to XCNT. An out-of-range maximum condition occurs when the count is greater than XMAX. Note that the XMIN and XMAX fields are 8-bit unsigned values, and the comparison is performed using unsigned arithmetic.

An out-of-range count may indicate either that an unstable clock was detected, or that the audio source has changed and a new sample rate is being used.

In order for the transmit clock failure check circuit to operate correctly, the high-frequency serial clock divider must be taken out of reset regardless if AHCLKX is internally generated or externally sourced.

Figure 21-16. Transmit Clock Failure Detection Circuit Block Diagram

A Refer to device data manual for the McASP system clock source. This is not the same as AUXCLK.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

The following actions are taken if a clock failure is detected:

1. Transmit clock failure flag (XCKFAIL) in XSTAT is set. This causes an interrupt if transmit clock failure interrupt enable bit (XCKFAIL) in XINTCTL is set.

In addition (only supported for DIT mode), if the transmit clock failure detect autoswitch enable bit (XCKFAILSW) in XCLKCHK is set, the following additional steps are taken to change the clock source from external to internal:

1. High-frequency transmit clock source bit (HCLKXM) in AHCLKXCTL is set to 1 and internal serial clock divider is selected. However, AHCLKX pin direction does not change to an output while XCKFAIL is set.
2. The internal clock divider is reset, so that the next clock it produces is a full period. However, the transmit clock divide ratio bits (HCLKXDIV) in AHCLKXCTL are not affected, so the internal clock divider generates clocks at the rate configured.
3. The transmit section is reset for a single serial clock period.
4. The transmit section is released from reset and attempts to begin transmitting. If data is available, it begins transmitting immediately; otherwise, it enters the underrun state. An initial underrun is certain to occur, the pattern 1100 (BMC zeroes) should be shifted out initially.

To change back to an external clock, take the following actions:

1. Wait for the external clock to stabilize again. This can be checked by polling the transmit clock count (XCNT) in XCLKCHK.
2. Reset the transmit section according to the startup procedure in Section 21.3.8.4.6.1.

21.3.8.4.6.3 Receive Clock Failure Check and Recovery

The receive clock failure check circuit (Figure 21-17) works off both the internal McASP system clock and the external high-frequency serial clock (AHCLKR). It continually counts the number of system clocks for every 32 high rate serial clock (AHCLKR) periods, and stores the count in RCNT of the receive clock check control register (RCLKCHK) every 32 high rate serial clock cycles.

The logic compares the count against a user-defined minimum allowable boundary (RMIN) and automatically flags an interrupt (RCKFAIL in RSTAT) when an out-of-range condition occurs. An out-of-range minimum condition occurs when the count is smaller than RMIN. The logic continually compares the current count (from the running system clock counter) against the maximum allowable boundary (RMAX). This is in case the external clock completely stops, so that the counter value is not copied to RCNT. An out-of-range maximum condition occurs when the count is greater than RMAX. Note that the RMIN and RMAX fields are 8-bit unsigned values, and the comparison is performed using unsigned arithmetic.

An out-of-range count may indicate either that an unstable clock was detected or that the audio source has changed and a new sample rate is being used.

In order for the receive clock failure check circuit to operate correctly, the high-frequency serial clock divider must be taken out of reset regardless if AHCLKR is internally generated or externally sourced.

Figure 21-17. Receive Clock Failure Detection Circuit Block Diagram

A Refer to device data manual for the McASP system clock source. This is not the same as AUXCLK.

21.3.8.5 Loopback Modes

The McASP features a digital loopback mode (DLB) that allows testing of the McASP code in TDM mode with a single processor device. In loopback mode, output of the transmit serializers is connected internally to the input of the receive serializers. Therefore, you can check the receive data against the transmit data to ensure that the McASP settings are correct. Digital loopback mode applies to TDM mode only (2 to 32 slots in a frame). It does not apply to DIT mode (XMOD = 180h) or burst mode (XMOD = 0).

Figure 21-18 shows the basic logical connection of the serializers in loopback mode. Two types of loopback connections are possible, selected by the ORD bit in the digital loopback control register (DLBCTL) as follows:

- ORD = 0: Outputs of odd serializers are connected to inputs of even serializers. If this mode is selected, you should configure odd serializers to be transmitters and even serializers to be receivers.
- ORD = 1: Outputs of even serializers are connected to inputs of odd serializers. If this mode is selected, you should configure even serializers to be transmitters and odd serializers to be receivers.

Data can be externally visible at the I/O pin of the transmit serializer if the pin is configured as a McASP output pin by setting the corresponding PFUNC bit to 0 and PDIR bit to 1.

In loopback mode, the transmit clock and frame sync are used by both the transmit and receive sections of the McASP. The transmit and receive sections operate synchronously. This is achieved by setting the MODE bit of the DLBCTL register to 01b and the ASYNC bit of the ACLKXCTL register to 0.

Figure 21-18. Serializers in Loopback Mode

(a) DLBEN = 1 (loopback enabled) and ORD = 0 (even receive, odd transmit)

(b) DLBEN = 1 (loopback enabled) and ORD = 1 (odd receive, even transmit)

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

21.3.8.5.1 Loopback Mode Configurations

This is a summary of the settings required for digital loopback mode for TDM format:

- The DLBEN bit in DLBCTL must be set to 1 to enable loopback mode.
- The MODE bits in DLBCTL must be set to 01b for both the transmit and receive sections to use the transmit clock and frame sync generator.
- The ORD bit in DLBCTL must be programmed appropriately to select odd or even serializers to be transmitters or receivers. The corresponding serializers must be configured accordingly.
- The ASYNC bit in ACLKXCTL must be cleared to 0 to ensure synchronous transmit and receive operations.
- RMOD field in AFSRCTL and XMOD field in AFSXCTL must be set to 2h to 20h to indicate TDM mode. Loopback mode does not apply to DIT or burst mode.

21.3.9 Reset Considerations

The McASP has two reset sources: software reset and hardware reset.

21.3.9.1 Software Reset Considerations

The transmitter and receiver portions of the McASP may be put in reset through the global control register (GBLCTL). Note that a valid serial clock must be supplied to the desired portion of the McASP (transmit and/or receive) in order to assert the software reset bits in GBLCTL. see Section 21.3.10.2for details on how to ensure reset has occurred.

The entire McASP module may also be reset through the Power and Sleep Controller (PSC). Note that from the McASP perspective, this reset appears as a hardware reset to the entire module.

21.3.9.2 Hardware Reset Considerations

When the McASP is reset due to device reset, the entire serial port (including the transmitter and receiver state machines, and other registers) is reset.

21.3.10 Setup and Initialization

This section discusses steps necessary to use the McASP module.

21.3.10.1 Considerations When Using a McASP

The following is a list of things to be considered for systems using a McASP:

21.3.10.1.1 Clocks

For each receive and transmit section:

- External or internal generated bit clock and high frequency clock?
- If internally generated, what is the bit clock speed and the high frequency clock speed?
- Clock polarity?
- External or internal generated frame sync?
- If internally generated, what is frame sync speed?
- Frame sync polarity?
- Frame sync width?
- Transmit and receive sync or asynchronous?

21.3.10.1.2 Data Pins

For each pin of each McASP:

- McASP or GPIO?
- Input or output?

Copyright © 2011, Texas Instruments Incorporated

21.3.10.1.3 Data Format

For each transmit and receive data:

- Internal numeric representation (integer, Q31 fraction)?
- I2S or DIT (transmit only)?
- Time slot delay (0, 1, or 2 bit)?
- Alignment (left or right)?
- Order (MSB first, LSB first)?
- Pad (if yes, pad with what value)?
- Slot size?
- Rotate?
- Mask?

21.3.10.1.4 Data Transfers

- Internal: DMA or CPU?
- External: TDM or burst?
- Bus: configuration bus (CFG) or data port (DAT)?

21.3.10.2 Transmit/Receive Section Initialization

You must follow the following steps to properly configure the McASP. If external clocks are used, they should be present prior to the following initialization steps.

1. Reset McASP to default values by setting GBLCTL = 0.
2. Configure all McASP registers except GBLCTL in the following order:
   (a) Power down and emulation management: PWRDEMU.
   (b) Receive registers: RMASK, RFMT, AFSRCTL, ACLKRCTL, AHCLKRCTL, RTDM, RINTCTL, RCLKCHK. If external clocks AHCLKR and/or ACLKR are used, they must be running already for proper synchronization of the GBLCTL register.
   (c) Transmit registers: XMASK, XFMT, AFSXCTL, ACLKXCTL, AHCLKXCTL, XTDM, XINTCTL, XCLKCHK. If external clocks AHCLKX and/or ACLKX are used, they must be running already for proper synchronization of the GBLCTL register.
   (d) Serializer registers: SRCTL[n].
   (e) Global registers: Registers PFUNC, PDIR, DITCTL, DLBCTL, AMUTE. Note that PDIR should only be programmed after the clocks and frames are set up in the steps above. This is because the moment a clock pin is configured as an output in PDIR, the clock pin starts toggling at the rate defined in the corresponding clock control register. Therefore you must ensure that the clock control register is configured appropriately before you set the pin to be an output. A similar argument applies to the frame sync pins. Also note that the reset state for the transmit high-frequency clock divide register (HCLKXDIV) is divide-by-1, and the divide-by-1 clocks are not gated by the transmit high-frequency clock divider reset enable (XHCLKRST).
   (f) DIT registers: For DIT mode operation, set up registers DITCSRA[n], DITCSRB[n], DITUDRA[n], and DITUDRB[n].
3. Start the respective high-frequency serial clocks AHCLKX and/or AHCLKR. This step is necessary even if external high-frequency serial clocks are used:
   (a) Take the respective internal high-frequency serial clock divider(s) out of reset by setting the RHCLKRST bit for the receiver and/or the XHCLKRST bit for the transmitter in GBLCTL. All other bits in GBLCTL should be held at 0.
   (b) Read back from GBLCTL to ensure the bit(s) to which you wrote are successfully latched in GBLCTL before you proceed.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

4. Start the respective serial clocks ACLKX and/or ACLKR. This step can be skipped if external serial clocks are used and they are running:
   (a) Take the respective internal serial clock divider(s) out of reset by setting the RCLKRST bit for the receiver and/or the XCLKRST bit for the transmitter in GBLCTL. All other bits in GBLCTL should be left at the previous state.
   (b) Read back from GBLCTL to ensure the bit(s) to which you wrote are successfully latched in GBLCTL before you proceed.
5. Setup data acquisition as required:
   (a) If DMA is used to service the McASP, set up data acquisition as desired and start the DMA in this step, before the McASP is taken out of reset.
   (b) If CPU interrupt is used to service the McASP, enable the transmit and/ or receive interrupt as required.
   (c) If CPU polling is used to service the McASP, no action is required in this step.
6. Activate serializers.
   (a) Before starting, clear the respective transmitter and receiver status registers by writing XSTAT = FFFFh and RSTAT = FFFFh.
   (b) Take the respective serializers out of reset by setting the RSRCLR bit for the receiver and/or the XSRCLR bit for the transmitter in GBLCTL. All other bits in GBLCTL should be left at the previous state.
   (c) Read back from GBLCTL to ensure the bit(s) to which you wrote are successfully latched in GBLCTL before you proceed.
7. Verify that all transmit buffers are serviced. Skip this step if the transmitter is not used. Also, skip this step if time slot 0 is selected as inactive (special cases, see Figure 21-6, second waveform). As soon as the transmit serializer is taken out of reset, XDATA in the XSTAT register is set, indicating that XBUF is empty and ready to be serviced. The XDATA status causes an DMA event AXEVT to be generated, and can cause an interrupt AXINT to be generated if it is enabled in the XINTCTL register.
   (a) If DMA is used to service the McASP, the DMA automatically services the McASP upon receiving AXEVT. Before proceeding in this step, you should verify that the XDATA bit in the XSTAT is cleared to 0, indicating that all transmit buffers are already serviced by the DMA.
   (b) If CPU interrupt is used to service the McASP, interrupt service routine is entered upon the AXINT interrupt. The interrupt service routine should service the XBUF registers. Before proceeding in this step, you should verify that the XDATA bit in XSTAT is cleared to 0, indicating that all transmit buffers are already serviced by the CPU.
   (c) If CPU polling is used to service the McASP, the XBUF registers should be written to in this step.
8. Release state machines from reset.
   (a) Take the respective state machine(s) out of reset by setting the RSMRST bit for the receiver and/or the XSMRST bit for the transmitter in GBLCTL. All other bits in GBLCTL should be left at the previous state.
   (b) Read back from GBLCTL to ensure the bit(s) to which you wrote are successfully latched in GBLCTL before you proceed.
9. Release frame sync generators from reset. Note that it is necessary to release the internal frame sync generators from reset, even if an external frame sync is being used, because the frame sync error detection logic is built into the frame sync generator.
   (a) Take the respective frame sync generator(s) out of reset by setting the RFRST bit for the receiver, and/or the XFRST bit for the transmitter in GBLCTL. All other bits in GBLCTL should be left at the previous state.
   (b) Read back from GBLCTL to ensure the bit(s) to which you wrote are successfully latched in GBLCTL before you proceed.
10. Upon the first frame sync signal, McASP transfers begin. The McASP synchronizes to an edge on the frame sync pin, not the level on the frame sync pin. This makes it easy to release the state machine and frame sync generators from reset.
   (a) For example, if you configure the McASP for a rising edge transmit frame sync, then you do not need to wait for a low level on the frame sync pin before releasing the McASP transmitter state

21.3.10.3 Separate Transmit and Receive Initialization

In many cases, it is desirable to separately initialize the McASP transmitter and receiver. For example, you may delay the initialization of the transmitter until the type of data coming in on the receiver is recognized. Or a change in the incoming data stream on the receiver may necessitate a reinitialization of the transmitter.

In this case, you may still follow the sequence outlined in Section 21.3.10.2, but use it for each section (transmit, receive) individually. The GBLCTL register is aliased to RGBLCTL and XGBLCTL to facilitate separate initialization of transmit and receive sections.

21.3.10.4 Importance of Reading Back GBLCTL

In Section 21.3.10.2, steps 3b, 4b, 6c, 8b, and 9b state that GBLCTL should be read back until the bits that were written are successfully latched. This is important, because the transmitter and receiver state machines run off of the respective bit clocks, which are typically about tens to hundreds of times slower than the processor's internal bus clock. Therefore, it takes many cycles between when the processor writes to GBLCTL (or RGBLCTL and XGBLCTL), and when the McASP actually recognizes the write operation. If you skip this step, then the McASP may never see the reset bits in the global control registers get asserted and de-asserted; resulting in an uninitialized McASP.

Therefore, the logic in McASP has been implemented such that once the processor writes GBLCTL, RGBLCTL, or XGBLCTL, the resulting write is not visible by reading back GBLCTL until the McASP has recognized the change. This typically requires two bit clocks plus two processor bus clocks to occur.

Also, if the bit clocks can be completely stopped, any software that polls GBLCTL should be implemented with a time-out. If GBLCTL does not have a time-out, and the bit clock stops, the changes written to GBLCTL will not be reflected until the bit clock restarts.

Finally, please note that while RGBLCTL and XGBLCTL allow separate changing of the receive and transmit halves of GBLCTL, they also immediately reflect the updated value (useful for debug purposes). Only GBLCTL can be used for the read back step.

21.3.10.5 Synchronous Transmit and Receive Operation (ASYNC = 0)

When ASYNC = 0 in ACLKXCTL, the transmit and receive sections operate synchronously from the transmit section clock and transmit frame sync signals (Figure 21-2). The receive section may have a different (but compatible in terms of slot size) data format.

When ASYNC = 0, the receive frame sync generator is internally disabled. If the AFSX pin is configured as an output, it serves as the frame sync signal for both transmit and receive. The AFSR pin should not be used because the transmit frame sync generator output, which is used by both the transmitter and the receiver when ASYNC = 0, is not propagated to the AFSR pin (Figure 21-4).

When ASYNC = 0, the transmit and receive sections must share some common settings, since they both use the same clock and frame sync signals:

- DITEN = 0 in DITCTL (TDM mode is enabled).
- The total number of bits per frame must be the same (that is, RSSZ × RMOD must equal XSSZ × XMOD).
- Both transmit and receive should either be specified as burst or TDM mode, but not mixed.
- The settings in ACLKRCTL are irrelevant.
- FSXM must match FSRM.
- FXWID must match FRWID.

For all other settings, the transmit and receive sections may be programmed independently.

21.3.10.6 Asynchronous Transmit and Receive Operation (ASYNC = 1)

When ASYNC = 1 in ACLKXCTL, the transmit and receive sections operate completely independently and have separate clock and frame sync signals (Figure 21-2, Figure 21-3, and Figure 21-4). The events generated by each section come asynchronously.

21.3.11 Interrupts

21.3.11.1 Interrupt Multiplexing

The processor includes an interrupt controller (INTC) to manage CPU interrupts. The INTC maps the device events to 12 CPU interrupts. The McASP generates 4 interrupts to the processor.

The event inputs can be routed to 12 maskable interrupts to the CPU (INT[15:4]). The INTC interrupt selector allows the McASP system events to be routed to any of the 12 CPU interrupt inputs. Furthermore, the INTC provides status flags and allows the combination of events, as shown in Figure 21-19. You must properly configure the INTC by enabling, masking, and routing the McASP system events to the desired CPU interrupts.

Figure 21-19. Interrupt Multiplexing

21.3.11.2 Transmit Data Ready Interrupt

The transmit data ready interrupt (XDATA) is generated if XDATA is 1 in the XSTAT register and XDATA is also enabled in XINTCTL. Section 21.3.8.1.1 provides details on when XDATA is set in the XSTAT register.

A transmit start of frame interrupt (XSTAFRM) is triggered by the recognition of transmit frame sync. A transmit last slot interrupt (XLAST) is a qualified version of the data ready interrupt (XDATA). It has the same behavior as the data ready interrupt, but is further qualified by having the data requested belonging to the last slot (the slot that just ended was next-to-last TDM slot, current slot is last slot).

21.3.11.3 Receive Data Ready Interrupt

The receive data ready interrupt (RDATA) is generated if RDATA is 1 in the RSTAT register and RDATA is also enabled in RINTCTL. Section 21.3.8.1.2 provides details on when RDATA is set in the RSTAT register.

A receiver start of frame interrupt (RSTAFRM) is triggered by the recognition of a receiver frame sync. A receiver last slot interrupt (RLAST) is a qualified version of the data ready interrupt (RDATA). It has the same behavior as the data ready interrupt, but is further qualified by having the data in the buffer come from the last TDM time slot (the slot that just ended was last TDM slot).

21.3.11.4 Error Interrupts

Upon detection, the following error conditions generate interrupt flags:

- In the receive status register (RSTAT):
  - Receiver overrun (ROVRN).
  - Unexpected receive frame sync (RSYNCERR).
  - Receive clock failure (RCKFAIL).
  - Receive DMA error (RDMAERR).

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

- In the transmit status register (XSTAT):
  - Transmit underrun (XUNDRN).
  - Unexpected transmit frame sync (XSYNCERR).
  - Transmit clock failure (XCKFAIL).
  - Transmit DMA error (XDMAERR).

Each interrupt source also has a corresponding enable bit in the receive interrupt control register (RINTCTL) and transmit interrupt control register (XINTCTL). If the enable bit is set in RINTCTL or XINTCTL, an interrupt is requested when the interrupt flag is set in RSTAT or XSTAT. If the enable bit is not set, no interrupt request is generated. However, the interrupt flag may be polled.

21.3.11.5 Audio Mute (AMUTE) Function

The McASP includes an automatic audio mute function (Figure 21-20) that asserts in hardware the AMUTE pin to a preprogrammed output state, as selected by the MUTEN bit in the audio mute control register (AMUTE). The AMUTE pin is asserted when one of the interrupt flags is set or an external device issues an error signal on the AMUTEIN input. Typically, the AMUTEIN input is shared with a device interrupt pin (for example EXT_INT4).

The AMUTEIN input allows the on-chip logic to consider a mute input from other devices in the system, so that all errors may be considered. The AMUTEIN input has a programmable polarity to allow it to adapt to different devices, as selected by the INPOL bit in AMUTE, and it must be enabled explicitly.

In addition to the external AMUTEIN input, the AMUTE pin output may be asserted when one of the error interrupt flags is set and its mute function is enabled in AMUTE.

When one or more of the errors is detected and enabled, the AMUTE pin is driven to an active state that is selected by MUTEN in AMUTE. The active polarity of the AMUTE pin is programmable by MUTEN (and the inactive polarity is the opposite of the active polarity). The AMUTE pin remains driven active until software clears all the error interrupt flags that are enabled to mute, and until the AMUTEIN is inactive.

21.3.11.6 Multiple Interrupts

This only applies to interrupts and not to DMA requests. The following terms are defined:

- **Active Interrupt Request:** a flag in RSTAT or XSTAT is set and the interrupt is enabled in RINTCTL or XINTCTL.
- **Outstanding Interrupt Request:** An interrupt request has been issued on one of the McASP transmit/receive interrupt ports, but that request has not yet been serviced.
- **Serviced:** The CPU writes to RSTAT or XSTAT to clear one or more of the active interrupt request flags.

The first interrupt request to become active for the transmitter with the interrupt flag set in XSTAT and the interrupt enabled in XINTCTL generates a request on the McASP transmit interrupt port AXINT.

If more than one interrupt request becomes active in the same cycle, a single interrupt request is generated on the McASP transmit interrupt port. Subsequent interrupt requests that become active while the first interrupt request is outstanding do not immediately generate a new request pulse on the McASP transmit interrupt port.

The transmit interrupt is serviced with the CPU writing to XSTAT. If any interrupt requests are active after the write, a new request is generated on the McASP transmit interrupt port.

The receiver operates in a similar way, but using RSTAT, RINTCTL, and the McASP receive interrupt port ARINT.

One outstanding interrupt request is allowed on each port, so a transmit and a receive interrupt request may both be outstanding at the same time.

21.3.12 EDMA Event Support

21.3.12.1 EDMA Events

There are 6 EDMA events.

21.3.12.2 Using the DMA for McASP Servicing

The most typical scenario is to use the DMA to service the McASP through the data port, although the DMA can also service the McASP through the configuration bus. Two possibilities exist for using the DMA events to service the McASP:

1. Use **AXEVT/AREVT**: Triggered upon each XDATA/RDATA transition from 0 to 1.
2. Use **AXEVTO/AREVTO** and **AXEVTE/AREVTE**: Alternating AXEVT/AREVT events for odd/even slots. Upon AXEVT/AREVT, AXEVTO/AREVTO is triggered if the event is for an odd channel, and AXEVTE/AREVTE is triggered if the event is for an even channel.

NOTE: Check the device-specific data manual to see if AXEVTO/AREVTO and AXEVTE/AREVTE are supported. These are optional.

Figure 21-21 and Figure 21-22 show an example audio system with six audio channels (LF, RF, LS, RS, C, and LFE) transmitted from three AXRn pins on the McASP. Figure 21-21 and Figure 21-22 show when events AXEVT, AXEVTO, and AXEVTE are triggered. Figure 21-21 and Figure 21-22 also apply for the receive audio channels and show when events AREVT, AREVTO, and AREVTE are triggered.

You can either use the DMA to service the McASP upon events AXEVT and AREVT (Figure 21-21) or upon events AXEVTO, AREVTO, AXEVTE, and AREVTE (Figure 21-22).

Figure 21-21. DMA Events in an Audio Example–Two Events (Scenario 1)

Figure 21-22. DMA Events in an Audio Example–Four Events (Scenario 2)

In scenario 1 (Figure 21-21), a DMA event AXEVT/AREVT is triggered on each time slot. In the example, AXEVT is triggered for each of the transmit audio channel time slot (Time slot for channels LF, LS, and C; and time slot for channels RF, RS, LFE). Similarly, AREVT is triggered for each of the receive audio channel time slot. Scenario 1 allows for the use of a single DMA to transmit all audio channels, and a single DMA to receive all audio channels.

In scenario 2 (Figure 21-22), two alternating DMA events are triggered for each time slot. In the example, AXEVTE (even) is triggered for the time slot for the even audio channels (LF, LS, C) and AXEVTO (odd) is triggered for the time slot for the odd audio channels (RF, RS, LFE). AXEVTO and AXEVTE alternate in time. The same is true in the receive direction with the use of AREVTO and AREVTE. This scenario allows for the use of two DMA channels (odd and even) to transmit all audio channels, and two DMA channels to receive all audio channels.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Here are some guidelines on using the different DMA events:

- Either use AXEVT, or the combination of AXEVTO and AXEVTE, to service the McASP. Never use all three at the same time. Similarly for receive, either use AREVT, or the combination of AREVTO and AREVTE.
- The McASP generates transmit DMA events independently from receive DMA events; therefore, separate schemes can be used for transmit and receive DMA. For example, scenario 1 could be used for the transmit data (AXEVT) and scenario 2 could be used for the receive data (AREVTO, AREVTE), and conversely.

Note the difference between DMA event generation and the CPU interrupt generation. DMA events are generated automatically upon data ready; whereas CPU interrupt generation needs to be enabled in the XINTCTL/RINTCTL register.

In Figure 21-22, scenario 2, each transmit DMA request is for data in the next time slot, while each receive DMA request is for data in the previous time slot. For example, Figure 21-23 shows a circled AXEVTE event for an even time slot transmit DMA request. The transmitter always requests a DMA transfer for data it will need to transmit during the next time slot. So, in this example, the circled event AXEVTE is a request for data for samples LF2, LS2, and C2.

On the other hand, the circled AREVTE event is an even time slot receive DMA request. The receiver always requests a DMA transfer for data it received during the previous time slot. In this example, the circled event AREVTE is a request for samples LF1, LS1, and C1.

Figure 21-23. DMA Events in an Audio Example

21.3.13 Power Management

The McASP can be placed in reduced power modes to conserve power during periods of low activity.

21.3.14 Emulation Considerations

NOTE: The receive buffer registers (RBUF*n*) and transmit buffer registers (XBUF*n*) should not be accessed by the emulator when the McASP is running. Such an access will cause the RRDY/XRDY bit in the serializer control register *n* (SRCTL*n*) to be updated.

The McASP does not support the emulation suspend.

21.4 McASP Registers

Control registers for the McASP are summarized in Table 21-8. The control registers are accessed through the configuration bus of the device. The receive buffer registers (RBUF*n*) and transmit buffer registers (XBUF*n*) can also be accessed through the data port of the device, as listed in Table 21-9. See the device-specific data manual for the memory address of these registers.

Control registers for the McASP Audio FIFO (AFIFO) are summarized in Table 21-10. Note that the AFIFO Write FIFO (WFIFO) and Read FIFO (RFIFO) have independent control and status registers. The AFIFO control registers are accessed through the peripheral configuration port. See your device-specific data manual for the memory address of these registers.

21.4.2 Pin Function Register (PFUNC)

The pin function register (PFUNC) specifies the function of AXRn, ACLKX, AHCLKX, AFSX, ACLKR, AHCLKR, and AFSR pins as either a McASP pin or a general-purpose input/output (GPIO) pin. The PFUNC is shown in Figure 21-25 and described in Table 21-12.

CAUTION

Writing to Reserved Bits

Writing a value other than 0 to reserved bits in this register may cause improper device operation.

21.4.3 Pin Direction Register (PDIR)

The pin direction register (PDIR) specifies the direction of AXRn, ACLKX, AHCLKX, AFSX, ACLKR, AHCLKR, and AFSR pins as either an input or an output pin. The PDIR is shown in Figure 21-26 and described in Table 21-13.

Regardless of the pin function register (PFUNC) setting, each PDIR bit must be set to 1 for the specified pin to be enabled as an output and each PDIR bit must be cleared to 0 for the specified pin to be an input.

For example, if the McASP is configured to use an internally-generated bit clock and the clock is to be driven out to the system, the PFUNC bit must be cleared to 0 (McASP function) and the PDIR bit must be set to 1 (an output).

When AXRn is configured to transmit, the PFUNC bit must be cleared to 0 (McASP function) and the PDIR bit must be set to 1 (an output). Similarly, when AXRn is configured to receive, the PFUNC bit must be cleared to 0 (McASP function) and the PDIR bit must be cleared to 0 (an input).

CAUTION

Writing to Reserved Bits

Writing a value other than 0 to reserved bits in this register may cause improper device operation.

21.4.4 Pin Data Output Register (PDOUT)

The pin data output register (PDOUT) holds a value for data out at all times, and may be read back at all times. The value held by PDOUT is not affected by writing to PDIR and PFUNC. However, the data value in PDOUT is driven out onto the McASP pin only if the corresponding bit in PFUNC is set to 1 (GPIO function) and the corresponding bit in PDIR is set to 1 (output). When reading data, returns the corresponding bit value in PDOUT[n], does not return input from I/O pin; when writing data, writes to the corresponding PDOUT[n] bit. The PDOUT is shown in Figure 21-27 and described in Table 21-14.

PDOUT has these aliases or alternate addresses:

- PDSET - when written to at this address, writing a 1 to a bit in PDSET sets the corresponding bit in PDOUT to 1; writing a 0 has no effect and keeps the bits in PDOUT unchanged.
- PDCLR - when written to at this address, writing a 1 to a bit in PDCLR clears the corresponding bit in PDOUT to 0; writing a 0 has no effect and keeps the bits in PDOUT unchanged.

There is only one set of data out bits, PDOUT[31-0]. The other registers, PDSET and PDCLR, are just different addresses for the same control bits, with different behaviors during writes.

CAUTION

Writing to Reserved Bits

Writing a value other than 0 to reserved bits in this register may cause improper device operation.

21.4.5 Pin Data Input Register (PDIN)

The pin data input register (PDIN) holds the I/O pin state of each of the McASP pins. PDIN allows the actual value of the pin to be read, regardless of the state of PFUNC and PDIR. The value after reset for registers 1 through 15 and 24 through 31 depends on how the pins are being driven. The PDIN is shown in Figure 21-28 and described in Table 21-15.

CAUTION

Writing to Reserved Bits

Writing a value other than 0 to reserved bits in this register may cause improper device operation.

Figure 21-28. Pin Data Input Register (PDIN)

21.4.6 Pin Data Set Register (PDSET)

The pin data set register (PDSET) is an alias of the pin data output register (PDOUT) for writes only. Writing a 1 to the PDSET bit sets the corresponding bit in PDOUT and, if PFUNC = 1 (GPIO function) and PDIR = 1 (output), drives a logic high on the pin. PDSET is useful for a multitasking system because it allows you to set to a logic high only the desired pin(s) within a system without affecting other I/O pins controlled by the same McASP. The PDSET is shown in Figure 21-29 and described in Table 21-16.

CAUTION

Writing to Reserved Bits

Writing a value other than 0 to reserved bits in this register may cause improper device operation.

Figure 21-29. Pin Data Set Register (PDSET)

21.4.7 Pin Data Clear Register (PDCLR)

The pin data clear register (PDCLR) is an alias of the pin data output register (PDOUT) for writes only. Writing a 1 to the PDCLR bit clears the corresponding bit in PDOUT and, if PFUNC = 1 (GPIO function) and PDIR = 1 (output), drives a logic low on the pin. PDCLR is useful for a multitasking system because it allows you to clear to a logic low only the desired pin(s) within a system without affecting other I/O pins controlled by the same McASP. The PDCLR is shown in Figure 21-30 and described in Table 21-17.

CAUTION

Writing to Reserved Bits

Writing a value other than 0 to reserved bits in this register may cause improper device operation.

21.4.8 Global Control Register (GBLCTL)

The global control register (GBLCTL) provides initialization of the transmit and receive sections. The GBLCTL is shown in Figure 21-31 and described in Table 21-18.

The bit fields in GBLCTL are synchronized and latched by the corresponding clocks (ACLKX for bits 12-8 and ACLKR for bits 4-0). Before GBLCTL is programmed, you must ensure that serial clocks are running. If the corresponding external serial clocks, ACLKX and ACLKR, are not yet running, you should select the internal serial clock source in AHCLKXCTL, AHCLKRCTL, ACLKXCTL, and ACLKRCTL before GBLCTL is programmed. Also, after programming any bits in GBLCTL you should not proceed until you have read back from GBLCTL and verified that the bits are latched in GBLCTL.

Figure 21-31. Global Control Register (GBLCTL)

31						16

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 21-18. Global Control Register (GBLCTL) Field Descriptions

Bit	Field	Value	Description
31-13	Reserved	0	Reserved. The reserved bit location always returns the default value. A value written to this field has no effect. If writing to this field, always write the default value for future device compatibility.
12	XFRST		Transmit frame sync generator reset enable bit.
		0	Transmit frame sync generator is reset.
		1	Transmit frame sync generator is active. When released from reset, the transmit frame sync generator begins counting serial clocks and generating frame sync as programmed.
11	XSMRST		Transmit state machine reset enable bit.
		0	Transmit state machine is held in reset. AXRn pin state: If PFUNC[n] = 0 and PDIR[n] = 1; then the serializer drives the AXRn pin to the state specified for inactive time slot (as determined by DISMOD bits in SRCTL).
		1	Transmit state machine is released from reset. When released from reset, the transmit state machine immediately transfers data from XRBUF[n] to XRSR[n]. The transmit state machine sets the underrun flag (XUNDRN) in XSTAT, if XRBUF[n] have not been preloaded with data before reset is released. The transmit state machine also immediately begins detecting frame sync and is ready to transmit. Transmit TDM time slot begins at slot 0 after reset is released.
10	XSRCLR		Transmit serializer clear enable bit. By clearing then setting this bit, the transmit buffer is flushed to an empty state (XDATA = 1). If XSMRST = 1, XSRCLR = 1, XDATA = 1, and XBUF is not loaded with new data before the start of the next active time slot, an underrun will occur.
		0	Transmit serializers are cleared.
		1	Transmit serializers are active. When the transmit serializers are first taken out of reset (XSRCLR changes from 0 to 1), the transmit data ready bit (XDATA) in XSTAT is set to indicate XBUF is ready to be written.
9	XHCLKRST		Transmit high-frequency clock divider reset enable bit.
		0	Transmit high-frequency clock divider is held in reset and passes through its input as divide-by-1..
		1	Transmit high-frequency clock divider is running.
8	XCLKRST		Transmit clock divider reset enable bit.
		0	Transmit clock divider is held in reset. When the clock divider is in reset, it passes through a divide-by-1 of its input.
		1	Transmit clock divider is running.

		0	Drive is disabled. Detection of receiver overrun error is ignored by AMUTE.
		1	Drive is enabled (active). Upon detection of receiver overrun error, AMUTE is active and is driven according to MUTEN bit.
4	INSTAT		Determines drive on AXRn pin when PFUNC[n] and PDIR[n] bits are set to 1.
		0	AMUTEIN pin is inactive.
		1	AMUTEIN pin is active. Audio mute in error is detected.
3	INEN		Drive AMUTE active when AMUTEIN error is active (INSTAT = 1).
		0	Drive is disabled. AMUTEIN is ignored by AMUTE.
		1	Drive is enabled (active). INSTAT = 1 drives AMUTE active.
2	INPOL		Audio mute in (AMUTEIN) polarity select bit.
		0	Polarity is active high. A high on AMUTEIN sets INSTAT to 1.
		1	Polarity is active low. A low on AM UTEIN sets INSTAT to 1.
1-0	MUTEN	0-3h	AMUTE pin enable bit (unless overridden by GPIO registers).
		0	AMUTE pin is disabled, pin goes to tri-state condition.
		1h	AMUTE pin is driven high if error is detected.
		2h	AMUTE pin is driven low if error is detected.
		3h	Reserved

21.4.10 Digital Loopback Control Register (DLBCTL)

The digital loopback control register (DLBCTL) controls the internal loopback settings of the McASP in TDM mode. The DLBCTL is shown in Figure 21-33 and described in Table 21-20.

Figure 21-33. Digital Loopback Control Register (DLBCTL)

31															16
Reserved															
R-0															

15												4	3	2	1	0
Reserved													MODE		ORD	DLBEN
R-0													R/W-0		R/W-0	R/W-0

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 21-20. Digital Loopback Control Register (DLBCTL) Field Descriptions

Bit	Field	Value	Description
31-4	Reserved	0	Reserved. The reserved bit location always returns the default value. A value written to this field has no effect. If writing to this field, always write the default value for future device compatibility.
3-2	MODE	0-3h	Loopback generator mode bits. Applies only when loopback mode is enabled (DLBEN = 1).
		0	Default and reserved on loopback mode (DLBEN = 1). When in non-loopback mode (DLBEN = 0), MODE should be left at default (00). When in loopback mode (DLBEN = 1), MODE = 00 is reserved and is not applicable.
		1h	Transmit clock and frame sync generators used by both transmit and receive sections. When in loopback mode (DLBEN = 1), MODE must be 01.
		2h-3h	Reserved.
1	ORD		Loopback order bit when loopback mode is enabled (DLBEN = 1).
		0	Odd serializers N + 1 transmit to even serializers N that receive. The corresponding serializers must be programmed properly.
		1	Even serializers N transmit to odd serializers N + 1 that receive. The corresponding serializers must be programmed properly.
0	DLBEN		Loopback mode enable bit.
		0	Loopback mode is disabled.
		1	Loopback mode is enabled.

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 21-21. Digital Mode Control Register (DITCTL) Field Descriptions

Bit	Field	Value	Description
31-4	Reserved	0	Reserved. The reserved bit location always returns the default value. A value written to this field has no effect. If writing to this field, always write the default value for future device compatibility.
3	VB		Valid bit for odd time slots (DIT right subframe).
		0	V bit is 0 during odd DIT subframes.
		1	V bit is 1 during odd DIT subframes.
2	VA		Valid bit for even time slots (DIT left subframe).
		0	V bit is 0 during even DIT subframes.
		1	V bit is 1 during even DIT subframes.
1	Reserved	0	Reserved. The reserved bit location always returns the default value. A value written to this field has no effect. If writing to this field, always write the default value for future device compatibility.
0	DITEN		DIT mode enable bit. DITEN should only be changed while the XSMRST bit in GBLCTL is in reset (and for startup, XSRCLR also in reset). However, it is not necessary to reset the XCLKRST or XHCLKRST bits in GBLCTL to change DITEN.
		0	DIT mode is disabled. Transmitter operates in TDM or burst mode.
		1	DIT mode is enabled. Transmitter operates in DIT encoded mode.

21.4.12 Receiver Global Control Register (RGBLCTL)

Alias of the global control register (GBLCTL). Writing to the receiver global control register (RGBLCTL) affects only the receive bits of GBLCTL (bits 4-0). Reads from RGBLCTL return the value of GBLCTL. RGBLCTL allows the receiver to be reset independently from the transmitter. The RGBLCTL is shown in Figure 21-35 and described in Table 21-22. See Section 21.4.8 for a detailed description of GBLCTL.

Figure 21-35. Receiver Global Control Register (RGBLCTL)

Reserved		RFRST	RSMRST	RSRCLR	RHCLKRST	RCLKRST
R-0		R/W-0	R/W-0	R/W-0	R/W-0	R/W-0

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 21-22. Receiver Global Control Register (RGBLCTL) Field Descriptions

Bit	Field	Value	Description
31-13	Reserved	0	Reserved. The reserved bit location always returns the default value. A value written to this field has no effect. If writing to this field, always write the default value for future device compatibility.
12	XFRST	x	Transmit frame sync generator reset enable bit. A read of this bit returns the XFRST bit value of GBLCTL. Writes have no effect.
11	XSMRST	x	Transmit state machine reset enable bit. A read of this bit returns the XSMRST bit value of GBLCTL. Writes have no effect.
10	XSRCLR	x	Transmit serializer clear enable bit. A read of this bit returns the XSRCLR bit value of GBLCTL. Writes have no effect.
9	XHCLKRST	x	Transmit high-frequency clock divider reset enable bit. A read of this bit returns the XHCLKRST bit value of GBLCTL. Writes have no effect.
8	XCLKRST	x	Transmit clock divider reset enable bit. A read of this bit returns the XCLKRST bit value of GBLCTL. Writes have no effect.
7-5	Reserved	0	Reserved. The reserved bit location always returns the default value. A value written to this field has no effect. If writing to this field, always write the default value for future device compatibility.
4	RFRST		Receive frame sync generator reset enable bit. A write to this bit affects the RFRST bit of GBLCTL.
		0	Receive frame sync generator is reset.
		1	Receive frame sync generator is active.
3	RSMRST		Receive state machine reset enable bit. A write to this bit affects the RSMRST bit of GBLCTL.
		0	Receive state machine is held in reset.
		1	Receive state machine is released from reset.
2	RSRCLR		Receive serializer clear enable bit. A write to this bit affects the RSRCLR bit of GBLCTL.
		0	Receive serializers are cleared.
		1	Receive serializers are active.
1	RHCLKRST		Receive high-frequency clock divider reset enable bit. A write to this bit affects the RHCLKRST bit of GBLCTL.
		0	Receive high-frequency clock divider is held in reset and passes through its input as divide-by-1.
		1	Receive high-frequency clock divider is running.
0	RCLKRST		Receive clock divider reset enable bit. A write to this bit affects the RCLKRST bit of GBLCTL.
		0	Receive clock divider is held in reset.
		1	Receive clock divider is running.

21.4.13 Receive Format Unit Bit Mask Register (RMASK)

The receive format unit bit mask register (RMASK) determines which bits of the received data are masked off and padded with a known value before being read by the CPU or DMA. The RMASK is shown in Figure 21-36 and described in Table 21-23.

Figure 21-36. Receive Format Unit Bit Mask Register (RMASK)

31	0
RMASK[*n*]	
R/W-0	

LEGEND: R/W = Read/Write; -*n* = value after reset

Table 21-23. Receive Format Unit Bit Mask Register (RMASK) Field Descriptions

Bit	Field	Value	Description
31-0	RMASK[31-0]		Receive data mask *n* enable bit.
		0	Corresponding bit of receive data (after passing through reverse and rotate units) is masked out and then padded with the selected bit pad value (RPAD and RPBIT bits in RFMT).
		1	Corresponding bit of receive data (after passing through reverse and rotate units) is returned to CPU or DMA.

R/W-0	R/W-0	R/W-0	R/W-0	R/W-0	R/W-0

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 21-24. Receive Bit Stream Format Register (RFMT) Field Descriptions

Bit	Field	Value	Description
31-18	Reserved	0	Reserved. The reserved bit location always returns the default value. A value written to this field has no effect. If writing to this field, always write the default value for future device compatibility.
17-16	RDATDLY	0-3h	Receive bit delay.
		0	0-bit delay. The first receive data bit, AXRn, occurs in same ACLKR cycle as the receive frame sync (AFSR).
		1h	1-bit delay. The first receive data bit, AXRn, occurs one ACLKR cycle after the receive frame sync (AFSR).
		2h	2-bit delay. The first receive data bit, AXRn, occurs two ACLKR cycles after the receive frame sync (AFSR).
		3h	Reserved.
15	RRVRS		Receive serial bitstream order.
		0	Bitstream is LSB first. No bit reversal is performed in receive format bit reverse unit.
		1	Bitstream is MSB first. Bit reversal is performed in receive format bit reverse unit.
14-13	RPAD	0-3h	Pad value for extra bits in slot not belonging to the word. This field only applies to bits when RMASK[n] = 0.
		0	Pad extra bits with 0.
		1h	Pad extra bits with 1.
		2h	Pad extra bits with one of the bits from the word as specified by RPBIT bits.
		3h	Reserved.
12-8	RPBIT	0-1Fh	RPBIT value determines which bit (as read by the CPU or DMA from RBUF[n]) is used to pad the extra bits. This field only applies when RPAD = 2h.
		0	Pad with bit 0 value.
		1h-1Fh	Pad with bit 1 to bit 31 value.

Bit	Field	Value	Description
31-16	Reserved	0	Reserved. The reserved bit location always returns the default value. A value written to this field has no effect. If writing to this field, always write the default value for future device compatibility.
15-7	RMOD	0-1FFh	Receive frame sync mode select bits.
		0	Burst mode.
		1h	Reserved.
		2h-20h	2-slot TDM (I2S mode) to 32-slot TDM.
		21h-17Fh	Reserved.
		180h	384-slot TDM (external DIR IC inputting 384-slot DIR frames to McASP over I2S interface).
		181h-1FFh	Reserved.
6-5	Reserved	0	Reserved. The reserved bit location always returns the default value. A value written to this field has no effect. If writing to this field, always write the default value for future device compatibility.
4	FRWID		Receive frame sync width select bit indicates the width of the receive frame sync (AFSR) during its active period.
		0	Single bit.
		1	Single word.
3-2	Reserved	0	Reserved. The reserved bit location always returns the default value. A value written to this field has no effect. If writing to this field, always write the default value for future device compatibility.
1	FSRM		Receive frame sync generation select bit.
		0	Externally-generated receive frame sync.
		1	Internally-generated receive frame sync.
0	FSRP		Receive frame sync polarity select bit.
		0	A rising edge on receive frame sync (AFSR) indicates the beginning of a frame.
		1	A falling edge on receive frame sync (AFSR) indicates the beginning of a frame.

21.4.19 Receiver Interrupt Control Register (RINTCTL)

The receiver interrupt control register (RINTCTL) controls generation of the McASP receive interrupt (RINT). When the register bit(s) is set to 1, the occurrence of the enabled McASP condition(s) generates RINT. The RINTCTL is shown in Figure 21-42 and described in Table 21-29. See Section 21.4.20 for a description of the interrupt conditions.

Figure 21-42. Receiver Interrupt Control Register (RINTCTL)

Table 21-29. Receiver Interrupt Control Register (RINTCTL) Field Descriptions

Bit	Field	Value	Description
31-8	Reserved	0	Reserved. The reserved bit location always returns the default value. A value written to this field has no effect. If writing to this field, always write the default value for future device compatibility.
7	RSTAFRM		Receive start of frame interrupt enable bit.
		0	Interrupt is disabled. A receive start of frame interrupt does not generate a McASP receive interrupt (RINT).
		1	Interrupt is enabled. A receive start of frame interrupt generates a McASP receive interrupt (RINT).
6	Reserved	0	Reserved. The reserved bit location always returns the default value. A value written to this field has no effect. If writing to this field, always write the default value for future device compatibility.
5	RDATA		Receive data ready interrupt enable bit.
		0	Interrupt is disabled. A receive data ready interrupt does not generate a McASP receive interrupt (RINT).
		1	Interrupt is enabled. A receive data ready interrupt generates a McASP receive interrupt (RINT).
4	RLAST		Receive last slot interrupt enable bit.
		0	Interrupt is disabled. A receive last slot interrupt does not generate a McASP receive interrupt (RINT).
		1	Interrupt is enabled. A receive last slot interrupt generates a McASP receive interrupt (RINT).
3	RDMAERR		Receive DMA error interrupt enable bit.
		0	Interrupt is disabled. A receive DMA error interrupt does not generate a McASP receive interrupt (RINT).
		1	Interrupt is enabled. A receive DMA error interrupt generates a McASP receive interrupt (RINT).
2	RCKFAIL		Receive clock failure interrupt enable bit.
		0	Interrupt is disabled. A receive clock failure interrupt does not generate a McASP receive interrupt (RINT).
		1	Interrupt is enabled. A receive clock failure interrupt generates a McASP receive interrupt (RINT).
1	RSYNCERR		Unexpected receive frame sync interrupt enable bit.
		0	Interrupt is disabled. An unexpected receive frame sync interrupt does not generate a McASP receive interrupt (RINT).
		1	Interrupt is enabled. An unexpected receive frame sync interrupt generates a McASP receive interrupt (RINT).
0	ROVRN		Receiver overrun interrupt enable bit.
		0	Interrupt is disabled. A receiver overrun interrupt does not generate a McASP receive interrupt (RINT).
		1	Interrupt is enabled. A receiver overrun interrupt generates a McASP receive interrupt (RINT).

21.4.20 Receiver Status Register (RSTAT)

The receiver status register (RSTAT) provides the receiver status and receive TDM time slot number. If the McASP logic attempts to set an interrupt flag in the same cycle that the CPU writes to the flag to clear it, the McASP logic has priority and the flag remains set. This also causes a new interrupt request to be generated. The RSTAT is shown in Figure 21-43 and described in Table 21-30.

Figure 21-43. Receiver Status Register (RSTAT)

31						9	8
Reserved							RERR
R-0							R/W-0
7	6	5	4	3	2	1	0
RDMAERR	RSTAFRM	RDATA	RLAST	RTDMSLOT	RCKFAIL	RSYNCERR	ROVRN
R/W1C-0	R/W1C-0	R/W1C-0	R/W1C-0	R-0	R/W1C-0	R/W1C-0	R/W1C-0

LEGEND: R/W = Read/Write; R = Read only; W1C = Writing a 1 clears this bit; writing a 0 has no effect.; -*n* = value after reset

Table 21-30. Receiver Status Register (RSTAT) Field Descriptions

Bit	Field	Value	Description
31-9	Reserved	0	Reserved. The reserved bit location always returns the default value. A value written to this field has no effect. If writing to this field, always write the default value for future device compatibility.
8	RERR		RERR bit always returns a logic-OR of:ROVRN | RSYNCERR | RCKFAIL | RDMAERR Allows a single bit to be checked to determine if a receiver error interrupt has occurred.
		0	No errors have occurred.
		1	An error has occurred.
7	RDMAERR		Receive DMA error flag. RDMAERR is set when the CPU or DMA reads more serializers through the data port in a given time slot than were programmed as receivers. Causes a receive interrupt (RINT), if this bit is set and RDMAERR in RINTCTL is set. This bit is cleared by writing a 1 to this bit. Writing a 0 to this bit has no effect.
		0	Receive DMA error did not occur.
		1	Receive DMA error did occur.
6	RSTAFRM		Receive start of frame flag. Causes a receive interrupt (RINT), if this bit is set and RSTAFRM in RINTCTL is set. This bit is cleared by writing a 1 to this bit. Writing a 0 to this bit has no effect.
		0	No new receive frame sync (AFSR) is detected.
		1	A new receive frame sync (AFSR) is detected.
5	RDATA		Receive data ready flag. Causes a receive interrupt (RINT), if this bit is set and RDATA in RINTCTL is set. This bit is cleared by writing a 1 to this bit. Writing a 0 to this bit has no effect.
		0	No new data in RBUF.
		1	Data is transferred from XRSR to RBUF and ready to be serviced by the CPU or DMA. When RDATA is set, it always causes a DMA event (AREVT).
4	RLAST		Receive last slot flag. RLAST is set along with RDATA, if the current slot is the last slot in a frame. Causes a receive interrupt (RINT), if this bit is set and RLAST in RINTCTL is set. This bit is cleared by writing a 1 to this bit. Writing a 0 to this bit has no effect.
		0	Current slot is not the last slot in a frame.
		1	Current slot is the last slot in a frame. RDATA is also set.
3	RTDMSLOT		Returns the LSB of RSLOT. Allows a single read of RSTAT to determine whether the current TDM time slot is even or odd.
		0	Current TDM time slot is odd.
		1	Current TDM time slot is even.
2	RCKFAIL		Receive clock failure flag. RCKFAIL is set when the receive clock failure detection circuit reports an error (see *Clock Failure Detection*). Causes a receive interrupt (RINT), if this bit is set and RCKFAIL in RINTCTL is set. This bit is cleared by writing a 1 to this bit. Writing a 0 to this bit has no effect.
		0	Receive clock failure did not occur.
		1	Receive clock failure did occur.

Table 21-30. Receiver Status Register (RSTAT) Field Descriptions (continued)

Bit	Field	Value	Description
1	RSYNCERR		Unexpected receive frame sync flag. RSYNCERR is set when a new receive frame sync (AFSR) occurs before it is expected. Causes a receive interrupt (RINT), if this bit is set and RSYNCERR in RINTCTL is set. This bit is cleared by writing a 1 to this bit. Writing a 0 to this bit has no effect.
		0	Unexpected receive frame sync did not occur.
		1	Unexpected receive frame sync did occur.
0	ROVRN		Receiver overrun flag. ROVRN is set when the receive serializer is instructed to transfer data from XRSR to RBUF, but the former data in RBUF has not yet been read by the CPU or DMA. Causes a receive interrupt (RINT), if this bit is set and ROVRN in RINTCTL is set. This bit is cleared by writing a 1 to this bit. Writing a 0 to this bit has no effect.
		0	Receiver overrun did not occur.
		1	Receiver overrun did occur.

21.4.21 Current Receive TDM Time Slot Registers (RSLOT)

The current receive TDM time slot register (RSLOT) indicates the current time slot for the receive data frame. The RSLOT is shown in Figure 21-44 and described in Table 21-31.

Figure 21-44. Current Receive TDM Time Slot Registers (RSLOT)

31–16	15–9	8–0
Reserved	Reserved	RSLOTCNT
R-0	R-0	R-0

LEGEND: R = Read only; -*n* = value after reset

Table 21-31. Current Receive TDM Time Slot Registers (RSLOT) Field Descriptions

Bit	Field	Value	Description
31-9	Reserved	0	Reserved. The reserved bit location always returns the default value. A value written to this field has no effect. If writing to this field, always write the default value for future device compatibility.
8-0	RSLOTCNT	0-17Fh	Current receive time slot count. Legal values: 0 to 383 (17Fh). TDM function is not supported for > 32 time slots. However, TDM time slot counter may count to 383 when used to receive a DIR block (transferred over TDM format).

21.4.22 Receive Clock Check Control Register (RCLKCHK)

The receive clock check control register (RCLKCHK) configures the receive clock failure detection circuit. The RCLKCHK is shown in Figure 21-45 and described in Table 21-32.

Figure 21-45. Receive Clock Check Control Register (RCLKCHK)

31–24	23–16
RCNT	RMAX
R-0	R/W-0

15–8	7–4	3–0
RMIN	Reserved	RPS
R/W-0	R-0	R/W-0

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 21-32. Receive Clock Check Control Register (RCLKCHK) Field Descriptions

Bit	Field	Value	Description
31-24	RCNT	0-FFh	Receive clock count value (from previous measurement). The clock circuit continually counts the number of system clocks for every 32 receive high-frequency master clock (AHCLKR) signals, and stores the count in RCNT until the next measurement is taken.
23-16	RMAX	0-FFh	Receive clock maximum boundary. This 8-bit unsigned value sets the maximum allowed boundary for the clock check counter after 32 receive high-frequency master clock (AHCLKR) signals have been received. If the current counter value is greater than RMAX after counting 32 AHCLKR signals, RCKFAIL in RSTAT is set. The comparison is performed using unsigned arithmetic.
15-8	RMIN	0-FFh	Receive clock minimum boundary. This 8-bit unsigned value sets the minimum allowed boundary for the clock check counter after 32 receive high-frequency master clock (AHCLKR) signals have been received. If RCNT is less than RMIN after counting 32 AHCLKR signals, RCKFAIL in RSTAT is set. The comparison is performed using unsigned arithmetic.
7-4	Reserved	0	Reserved. The reserved bit location always returns the default value. A value written to this field has no effect. If writing to this field, always write the default value for future device compatibility.
3-0	RPS	0-Fh	Receive clock check prescaler value.
		0	McASP system clock divided by 1.
		1h	McASP system clock divided by 2.
		2h	McASP system clock divided by 4.
		3h	McASP system clock divided by 8.
		4h	McASP system clock divided by 16.
		5h	McASP system clock divided by 32.
		6h	McASP system clock divided by 64.
		7h	McASP system clock divided by 128.
		8h	McASP system clock divided by 256.
		9h-Fh	Reserved.

21.4.24 Transmitter Global Control Register (XGBLCTL)

Alias of the global control register (GBLCTL). Writing to the transmitter global control register (XGBLCTL) affects only the transmit bits of GBLCTL (bits 12-8). Reads from XGBLCTL return the value of GBLCTL. XGBLCTL allows the transmitter to be reset independently from the receiver. The XGBLCTL is shown in Figure 21-47 and described in Table 21-34. See Section 21.4.8 for a detailed description of GBLCTL.

Figure 21-47. Transmitter Global Control Register (XGBLCTL)

Table 21-34. Transmitter Global Control Register (XGBLCTL) Field Descriptions

Bit	Field	Value	Description
31-13	Reserved	0-FFh	Reserved. The reserved bit location always returns the default value. A value written to this field has no effect. If writing to this field, always write the default value for future device compatibility.
12	XFRST		Transmit frame sync generator reset enable bit. A write to this bit affects the XFRST bit of GBLCTL.
		0	Transmit frame sync generator is reset.
		1	Transmit frame sync generator is active.
11	XSMRST		Transmit state machine reset enable bit. A write to this bit affects the XSMRST bit of GBLCTL.
		0	Transmit state machine is held in reset.
		1	Transmit state machine is released from reset.
10	XSRCLR		Transmit serializer clear enable bit. A write to this bit affects the XSRCLR bit of GBLCTL.
		0	Transmit serializers are cleared.
		1	Transmit serializers are active.
9	XHCLKRST		Transmit high-frequency clock divider reset enable bit. A write to this bit affects the XHCLKRST bit of GBLCTL.
		0	Transmit high-frequency clock divider is held in reset.
		1	Transmit high-frequency clock divider is running.
8	XCLKRST		Transmit clock divider reset enable bit. A write to this bit affects the XCLKRST bit of GBLCTL.
		0	Transmit clock divider is held in reset.
		1	Transmit clock divider is running.
7-5	Reserved	0	Reserved. The reserved bit location always returns the default value. A value written to this field has no effect. If writing to this field, always write the default value for future device compatibility.
4	RFRST	x	Receive frame sync generator reset enable bit. A read of this bit returns the RFRST bit value of GBLCTL. Writes have no effect.
3	RSMRST	x	Receive state machine reset enable bit. A read of this bit returns the RSMRST bit value of GBLCTL. Writes have no effect.
2	RSRCLR	x	Receive serializer clear enable bit. A read of this bit returns the RSRSCLR bit value of GBLCTL. Writes have no effect.
1	RHCLKRST	x	Receive high-frequency clock divider reset enable bit. A read of this bit returns the RHCLKRST bit value of GBLCTL. Writes have no effect.
0	RCLKRST	x	Receive clock divider reset enable bit. A read of this bit returns the RCLKRST bit value of GBLCTL. Writes have no effect.

21.4.25 Transmit Format Unit Bit Mask Register (XMASK)

The transmit format unit bit mask register (XMASK) determines which bits of the transmitted data are masked off and padded with a known value before being shifted out the McASP. The XMASK is shown in Figure 21-48 and described in Table 21-35.

Figure 21-48. Transmit Format Unit Bit Mask Register (XMASK)

31	0
XMASK[*n*]	
R/W-0	

LEGEND: R/W = Read/Write; -*n* = value after reset

Table 21-35. Transmit Format Unit Bit Mask Register (XMASK) Field Descriptions

Bit	Field	Value	Description
31-0	XMASK[31-0]		Transmit data mask *n* enable bit.
		0	Corresponding bit of transmit data (before passing through reverse and rotate units) is masked out and then padded with the selected bit pad value (XPAD and XPBIT bits in XFMT), which is transmitted out the McASP in place of the original bit.
		1	Corresponding bit of transmit data (before passing through reverse and rotate units) is transmitted out the McASP.

R/W-0	R/W-0	R/W-0	R/W-0	R/W-0	R/W-0

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 21-36. Transmit Bit Stream Format Register (XFMT) Field Descriptions

Bit	Field	Value	Description
31-18	Reserved	0	Reserved. The reserved bit location always returns the default value. A value written to this field has no effect. If writing to this field, always write the default value for future device compatibility.
17-16	XDATDLY	0-3h	Transmit sync bit delay.
		0	0-bit delay. The first transmit data bit, AXRn, occurs in same ACLKX cycle as the transmit frame sync (AFSX).
		1h	1-bit delay. The first transmit data bit, AXRn, occurs one ACLKX cycle after the transmit frame sync (AFSX).
		2h	2-bit delay. The first transmit data bit, AXRn, occurs two ACLKX cycles after the transmit frame sync (AFSX).
		3h	Reserved.
15	XRVRS		Transmit serial bitstream order.
		0	Bitstream is LSB first. No bit reversal is performed in transmit format bit reverse unit.
		1	Bitstream is MSB first. Bit reversal is performed in transmit format bit reverse unit.
14-13	XPAD	0-3h	Pad value for extra bits in slot not belonging to word defined by XMASK. This field only applies to bits when XMASK[n] = 0.
		0	Pad extra bits with 0.
		1h	Pad extra bits with 1.
		2h	Pad extra bits with one of the bits from the word as specified by XPBIT bits.
		3h	Reserved.
12-8	XPBIT	0-1Fh	XPBIT value determines which bit (as written by the CPU or DMA to XBUF[n]) is used to pad the extra bits before shifting. This field only applies when XPAD = 2h.
		0	Pad with bit 0 value.
		1-1Fh	Pad with bit 1 to bit 31 value.

21.4.30 Transmit TDM Time Slot Register (XTDM)

The transmit TDM time slot register (XTDM) specifies in which TDM time slot the transmitter is active. TDM time slot counter range is extended to 384 slots (to support SPDIF blocks of 384 subframes). XTDM operates modulo 32, that is, XTDMS specifies the TDM activity for time slots 0, 32, 64, 96, 128, etc. The XTDM is shown in Figure 21-53 and described in Table 21-40.

Figure 21-53. Transmit TDM Time Slot Register (XTDM)

21.4.31 Transmitter Interrupt Control Register (XINTCTL)

The transmitter interrupt control register (XINTCTL) controls generation of the McASP transmit interrupt (XINT). When the register bit(s) is set to 1, the occurrence of the enabled McASP condition(s) generates XINT. The XINTCTL is shown in Figure 21-54 and described in Table 21-41. See Section 21.4.32 for a description of the interrupt conditions.

Figure 21-54. Transmitter Interrupt Control Register (XINTCTL)

Bit	Field	Value	Description
31-8	Reserved	0	Reserved. The reserved bit location always returns the default value. A value written to this field has no effect. If writing to this field, always write the default value for future device compatibility.
7	XSTAFRM		Transmit start of frame interrupt enable bit.
		0	Interrupt is disabled. A transmit start of frame interrupt does not generate a McASP transmit interrupt (XINT).
		1	Interrupt is enabled. A transmit start of frame interrupt generates a McASP transmit interrupt (XINT).
6	Reserved	0	Reserved. The reserved bit location always returns the default value. A value written to this field has no effect. If writing to this field, always write the default value for future device compatibility.
5	XDATA		Transmit data ready interrupt enable bit.
		0	Interrupt is disabled. A transmit data ready interrupt does not generate a McASP transmit interrupt (XINT).
		1	Interrupt is enabled. A transmit data ready interrupt generates a McASP transmit interrupt (XINT).
4	XLAST		Transmit last slot interrupt enable bit.
		0	Interrupt is disabled. A transmit last slot interrupt does not generate a McASP transmit interrupt (XINT).
		1	Interrupt is enabled. A transmit last slot interrupt generates a McASP transmit interrupt (XINT).
3	XDMAERR		Transmit DMA error interrupt enable bit.
		0	Interrupt is disabled. A transmit DMA error interrupt does not generate a McASP transmit interrupt (XINT).
		1	Interrupt is enabled. A transmit DMA error interrupt generates a McASP transmit interrupt (XINT).
2	XCKFAIL		Transmit clock failure interrupt enable bit.
		0	Interrupt is disabled. A transmit clock failure interrupt does not generate a McASP transmit interrupt (XINT).
		1	Interrupt is enabled. A transmit clock failure interrupt generates a McASP transmit interrupt (XINT).
1	XSYNCERR		Unexpected transmit frame sync interrupt enable bit.
		0	Interrupt is disabled. An unexpected transmit frame sync interrupt does not generate a McASP transmit interrupt (XINT).
		1	Interrupt is enabled. An unexpected transmit frame sync interrupt generates a McASP transmit interrupt (XINT).
0	XUNDRN		Transmitter underrun interrupt enable bit.
		0	Interrupt is disabled. A transmitter underrun interrupt does not generate a McASP transmit interrupt (XINT).
		1	Interrupt is enabled. A transmitter underrun interrupt generates a McASP transmit interrupt (XINT).

21.4.32 Transmitter Status Register (XSTAT)

The transmitter status register (XSTAT) provides the transmitter status and transmit TDM time slot number. If the McASP logic attempts to set an interrupt flag in the same cycle that the CPU writes to the flag to clear it, the McASP logic has priority and the flag remains set. This also causes a new interrupt request to be generated. The XSTAT is shown in Figure 21-55 and described in Table 21-42.

Figure 21-55. Transmitter Status Register (XSTAT)

31						9	8
Reserved							XERR
R-0							R/W-0

7	6	5	4	3	2	1	0
XDMAERR	XSTAFRM	XDATA	XLAST	XTDMSLOT	XCKFAIL	XSYNCERR	XUNDRN
R/W1C-0	R/W1C-0	R/W1C-0	R/W1C-0	R-0	R/W1C-0	R/W1C-0	R/W1C-0

LEGEND: R/W = Read/Write; R = Read only; W1C = Writing a 1 clears this bit; writing a 0 has no effect; -*n* = value after reset

Table 21-42. Transmitter Status Register (XSTAT) Field Descriptions

Bit	Field	Value	Description
31-9	Reserved	0	Reserved. The reserved bit location always returns the default value. A value written to this field has no effect. If writing to this field, always write the default value for future device compatibility.
8	XERR		XERR bit always returns a logic-OR of:XUNDRN | XSYNCERR | XCKFAIL | XDMAERR Allows a single bit to be checked to determine if a transmitter error interrupt has occurred.
		0	No errors have occurred.
		1	An error has occurred.
7	XDMAERR		Transmit DMA error flag. XDMAERR is set when the CPU or DMA writes more serializers through the data port in a given time slot than were programmed as transmitters. Causes a transmit interrupt (XINT), if this bit is set and XDMAERR in XINTCTL is set. This bit is cleared by writing a 1 to this bit. Writing a 0 has no effect.
		0	Transmit DMA error did not occur.
		1	Transmit DMA error did occur.
6	XSTAFRM		Transmit start of frame flag. Causes a transmit interrupt (XINT), if this bit is set and XSTAFRM in XINTCTL is set. This bit is cleared by writing a 1 to this bit. Writing a 0 has no effect.
		0	No new transmit frame sync (AFSX) is detected.
		1	A new transmit frame sync (AFSX) is detected.
5	XDATA		Transmit data ready flag. Causes a transmit interrupt (XINT), if this bit is set and XDATA in XINTCTL is set. This bit is cleared by writing a 1 to this bit. Writing a 0 has no effect.
		0	XBUF is written and is full.
		1	Data is copied from XBUF to XRSR. XBUF is empty and ready to be written. XDATA is also set when the transmit serializers are taken out of reset. When XDATA is set, it always causes a DMA event (AXEVT).
4	XLAST		Transmit last slot flag. XLAST is set along with XDATA, if the current slot is the last slot in a frame. Causes a transmit interrupt (XINT), if this bit is set and XLAST in XINTCTL is set. This bit is cleared by writing a 1 to this bit. Writing a 0 has no effect.
		0	Current slot is not the last slot in a frame.
		1	Current slot is the last slot in a frame. XDATA is also set.
3	XTDMSLOT		Returns the LSB of XSLOT. Allows a single read of XSTAT to determine whether the current TDM time slot is even or odd.
		0	Current TDM time slot is odd.
		1	Current TDM time slot is even.
2	XCKFAIL		Transmit clock failure flag. XCKFAIL is set when the transmit clock failure detection circuit reports an error (see *Clock Failure Detection*). Causes a transmit interrupt (XINT), if this bit is set and XCKFAIL in XINTCTL is set. This bit is cleared by writing a 1 to this bit. Writing a 0 has no effect.
		0	Transmit clock failure did not occur.
		1	Transmit clock failure did occur.

Table 21-42. Transmitter Status Register (XSTAT) Field Descriptions (continued)

Bit	Field	Value	Description
1	XSYNCERR		Unexpected transmit frame sync flag. XSYNCERR is set when a new transmit frame sync (AFSX) occurs before it is expected. Causes a transmit interrupt (XINT), if this bit is set and XSYNCERR in XINTCTL is set. This bit is cleared by writing a 1 to this bit. Writing a 0 has no effect.
		0	Unexpected transmit frame sync did not occur.
		1	Unexpected transmit frame sync did occur.
0	XUNDRN		Transmitter underrun flag. XUNDRN is set when the transmit serializer is instructed to transfer data from XBUF to XRSR, but XBUF has not yet been serviced with new data since the last transfer. Causes a transmit interrupt (XINT), if this bit is set and XUNDRN in XINTCTL is set. This bit is cleared by writing a 1 to this bit. Writing a 0 has no effect.
		0	Transmitter underrun did not occur.
		1	Transmitter underrun did occur. For details on McASP action upon underrun conditions, see *Buffer Underrun Error - Transmitter*.

21.4.33 Current Transmit TDM Time Slot Register (XSLOT)

The current transmit TDM time slot register (XSLOT) indicates the current time slot for the transmit data frame. The XSLOT is shown in Figure 21-56 and described in Table 21-43.

Figure 21-56. Current Transmit TDM Time Slot Register (XSLOT)

31–16	15–10	9–0
Reserved	Reserved	XSLOTCNT
R-0	R-0	R-17Fh

LEGEND: R = Read only; -*n* = value after reset

Table 21-43. Current Transmit TDM Time Slot Register (XSLOT) Field Descriptions

Bit	Field	Value	Description
31-10	Reserved	0	Reserved. The reserved bit location always returns the default value. A value written to this field has no effect. If writing to this field, always write the default value for future device compatibility.
9-0	XSLOTCNT	0-17Fh	Current transmit time slot count. Legal values: 0 to 383 (17Fh). During reset, this counter value is 383 so the next count value, which is used to encode the first DIT group of data, will be 0 and encodes the B preamble. TDM function is not supported for >32 time slots. However, TDM time slot counter may count to 383 when used to transmit a DIT block.

21.4.34 Transmit Clock Check Control Register (XCLKCHK)

The transmit clock check control register (XCLKCHK) configures the transmit clock failure detection circuit. The XCLKCHK is shown in Figure 21-57 and described in Table 21-44.

Figure 21-57. Transmit Clock Check Control Register (XCLKCHK)

31–24	23–16
XCNT	XMAX
R-0	R/W-0

15–8	7–4	3–0
XMIN	Reserved	XPS
R/W-0	R-0	R/W-0

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 21-44. Transmit Clock Check Control Register (XCLKCHK) Field Descriptions

Bit	Field	Value	Description
31-24	XCNT	0	Transmit clock count value (from previous measurement). The clock circuit continually counts the number of system clocks for every 32 transmit high-frequency master clock (AHCLKX) signals, and stores the count in XCNT until the next measurement is taken.
23-16	XMAX	0-FFh	Transmit clock maximum boundary. This 8-bit unsigned value sets the maximum allowed boundary for the clock check counter after 32 transmit high-frequency master clock (AHCLKX) signals have been received. If the current counter value is greater than XMAX after counting 32 AHCLKX signals, XCKFAIL in XSTAT is set. The comparison is performed using unsigned arithmetic.
15-8	XMIN	0-FFh	Transmit clock minimum boundary. This 8-bit unsigned value sets the minimum allowed boundary for the clock check counter after 32 transmit high-frequency master clock (AHCLKX) signals have been received. If XCNT is less than XMIN after counting 32 AHCLKX signals, XCKFAIL in XSTAT is set. The comparison is performed using unsigned arithmetic.
7-4	Reserved	0	Reserved. The reserved bit location always returns the default value. A value written to this field has no effect. If writing to this field, always write the default value for future device compatibility.
3-0	XPS	0-Fh	Transmit clock check prescaler value.
		0	McASP system clock divided by 1.
		1h	McASP system clock divided by 2.
		2h	McASP system clock divided by 4.
		3h	McASP system clock divided by 8.
		4h	McASP system clock divided by 16.
		5h	McASP system clock divided by 32.
		6h	McASP system clock divided by 64.
		7h	McASP system clock divided by 128.
		8h	McASP system clock divided by 256.
		9h-Fh	Reserved.

21.4.36 Serializer Control Registers (SRCTL*n*)

Each serializer on the McASP has a serializer control register (SRCTL). There are up to 6 serializers per McASP. The SRCTL is shown in Figure 21-59 and described in Table 21-46.

NOTE: Device-specific registers

Accessing SRCTL*n* not implemented on a specific device may cause improper device operation.

Figure 21-59. Serializer Control Registers (SRCTL*n*)

31–16	15–6	5	4	3–2	1–0
Reserved	Reserved	RRDY	XRDY	DISMOD	SRMOD
R-0	R-0	R-0	R-0	R/W-0	R/W-0

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 21-46. Serializer Control Registers (SRCTL*n*) Field Descriptions

Bit	Field	Value	Description
31-6	Reserved	0	Reserved. The reserved bit location always returns the default value. A value written to this field has no effect. If writing to this field, always write the default value for future device compatibility.
5	RRDY		Receive buffer ready bit. RRDY indicates the current receive buffer state. Always reads 0 when programmed as a transmitter or as inactive. If SRMOD bit is set to receive (2h), RRDY switches from 0 to 1 whenever data is transferred from XRSR to RBUF.
		0	Receive buffer (RBUF) is empty.
		1	Receive buffer (RBUF) contains data and needs to be read before the start of the next time slot or a receiver overrun occurs.
4	XRDY		Transmit buffer ready bit. XRDY indicates the current transmit buffer state. Always reads 0 when programmed as a receiver or as inactive. If SRMOD bit is set to transmit (1h), XRDY switches from 0 to 1 when XSRCLR in GBLCTL is switched from 0 to 1 to indicate an empty transmitter. XRDY remains set until XSRCLR is forced to 0, data is written to the corresponding transmit buffer, or SRMOD bit is changed to receive (2h) or inactive (0).
		0	Transmit buffer (XBUF) contains data.
		1	Transmit buffer (XBUF) is empty and needs to be written before the start of the next time slot or a transmit underrun occurs.
3-2	DISMOD	0-3h	Serializer pin drive mode bit. Drive on pin when in inactive TDM slot of transmit mode or when serializer is inactive. This field only applies if the pin is configured as a McASP pin (PFUNC = 0).
		0	Drive on pin is 3-state.
		1h	Reserved.
		2h	Drive on pin is logic low.
		3h	Drive on pin is logic high.
1-0	SRMOD	0-3h	Serializer mode bit.
		0	Serializer is inactive.
		1h	Serializer is transmitter.
		2h	Serializer is receiver.
		3h	Reserved.

21.4.37 DIT Left Channel Status Registers (DITCSRA0-DITCSRA5)

The DIT left channel status registers (DITCSRA) provide the status of each left channel (even TDM time slot). Each of the six 32-bit registers (Figure 21-60) can store 192 bits of channel status data for a complete block of transmission. The DIT reuses the same data for the next block. It is your responsibility to update the register file in time, if a different set of data need to be sent.

21.4.43 Write FIFO Control Register (WFIFOCTL)

The Write FIFO control register (WFIFOCTL) is shown in Figure 21-66 and described in Table 21-47.

NOTE: The WNUMEVT and WNUMDMA values must be set prior to enabling the Write FIFO.

If the Write FIFO is to be enabled, it must be enabled prior to taking the McASP out of reset.

22.1 Introduction

22.1.1 DCAN Features

The general features of the DCAN controller are:

- Supports CAN protocol version 2.0 part A, B (ISO 11898-1)
- Bit rates up to 1 MBit/s
- Dual clock source
- 16, 32, 64 or 128 message objects (instantiated as 64 on this device)
- Individual identifier mask for each message object
- Programmable FIFO mode for message objects
- Programmable loop-back modes for self-test operation
- Suspend mode for debug support
- Software module reset
- Automatic bus on after Bus-Off state by a programmable 32-bit timer
- Message RAM parity check mechanism
- Direct access to Message RAM during test mode
- CAN Rx / Tx pins configurable as general purpose IO pins
- Two interrupt lines (plus additional parity-error interrupt line)
- RAM initialization
- DMA support
- OCP interface up to 100 MHz (32b slave interface)

22.1.2 Unsupported DCAN Features

The DCAN module in this device does not support GPIO pin mode. All GPIO functionality is mapped through the GPIO modules and muxed at the pins. GPIO pin control signals from the DCAN modules are not connected.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

22.2 Integration

The Controller Area Network is a serial communications protocol which efficiently supports distributed realtime control with a high level of security. The DCAN module supports bitrates up to 1 Mbit/s and is compliant to the CAN 2.0B protocol specification. The core IP within DCAN is provided by Bosch.

This device includes two instantiations of the DCAN controller: DCAN0 and DCAN1. Figure 22-1 shows the DCAN module integration.

Figure 22-1. DCAN Integration

22.2.1 DCAN Connectivity Attributes

The general connectivity attributes for the DCAN module are shown in Table 22-1.

Table 22-1. DCAN Connectivity Attributes

Attributes	Type
Power Domain	Peripheral Domain
Clock Domain	PD_PER_L4LS_GCLK (OCP) PD_PER_CAN_CLK (Func)
Reset Signals	PER_DOM_RST_N
Idle/Wakeup Signals	Smart Idle
Interrupt Requests	3 Interrupts Intr0 – Error, Status, Msg Object interrupt Intr1 – Msg Object interrupt Uerr – Parity error interrupt All DCAN0 interrupts to MPU Subsystem and PRUSS. All DCAN1 interrupts to MPU Subsystem only.
DMA Requests	3 DMA requests to EDMA
Physical Address	L4 Peripheral slave port

22.2.2 DCAN Clock and Reset Management

The DCAN controllers have separate bus interface and functional clocks.

Table 22-2. DCAN Clock Signals

Clock Signal	Max Freq	Reference / Source	Comments
DCAN_ocp_clk Interface clock	100 MHz	CORE_CLKOUTM4 / 2	pd_per_l4ls_gclk from PRCM
DCAN_io_clk Functional clock	24 MHz	CLK_M_OSC	pd_per_can_clk from PRCM

22.2.3 DCAN Pin List

The external signals for the DCAN module are shown in the following table.

Table 22-3. DCAN Pin List

Pin	Type	Description
DCAN*x*_TX	O	DCAN transmit line
DCAN*x*_RX	I	DCAN receive line

22.3 Functional Description

The DCAN module performs CAN protocol communication according to ISO 11898-1. The bit rate can be programmed to values up to 1 MBit/s. Additional transceiver hardware is required for the connection to the physical layer (CAN bus).

For communication on a CAN network, individual message objects can be configured. The message objects and identifier masks are stored in the message RAM.

All functions concerning the handling of messages are implemented in the message handler. Those functions are acceptance filtering, the transfer of messages between the CAN core and the message RAM, and the handling of transmission requests, as well as the generation of interrupts or DMA requests.

The register set of the DCAN module can be accessed directly by the CPU via the module interface. These registers are used to control and configure the CAN core and the message handler, and to access the message RAM.

Figure 22-2 shows the DCAN block diagram and its features are described below.

Figure 22-2. DCAN Block Diagram

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

22.3.0.1 CAN Core

The CAN core consists of the CAN protocol controller and the Rx/Tx shift register. It handles all ISO 11898-1 protocol functions.

22.3.0.2 Message Handler

The message handler is a state machine that controls the data transfer between the single-ported message RAM and the CAN core's Rx/Tx shift register. It also handles acceptance filtering and the interrupt/DMA request generation as programmed in the control registers.

22.3.0.3 Message RAM

The DCAN0 and DCAN1 enables a storage of 64 CAN messages.

22.3.0.4 Message RAM Interface

Three interface register sets control the CPU read and write accesses to the message RAM. There are two interface registers sets for read and write access, IF1 and IF2, and one interface register set for read access only, IF3. Additional information can be found in Section 22.3.8.12.

The interface registers have the same word-length as the message RAM.

22.3.0.5 Registers and Message Object Access

Data consistency is ensured by indirect accesses to the message objects. During normal operation, all CPU and DMA accesses to the message RAM are done through interface registers. In a dedicated test mode, the message RAM is memory mapped and can be directly accessed by either CPU or DMA.

22.3.0.6 Module Interface

The DCAN module registers are accessed by the CPU or user software through a 32-bit peripheral bus interface.

22.3.0.7 Dual Clock Source

Two clock domains are provided to the DCAN module: the peripheral synchronous clock domain (L3_SLOW_GCLK) and the peripheral asynchronous clock source domain (OSC0) for CAN_CLK.

22.3.1 CAN Operation

After hardware reset, the Init bit in the CAN control register (DCAN CTL) is set and all CAN protocol functions are disabled. The CAN module must be initialized before operating it. Figure 22-3 illustrates the basic initialization flow for the CAN module.

22.3.1.1 CAN Module Initialization

A general CAN module initialization would mean the following two critical steps:

- Configuration of the CAN bit timing
- Configuration of message objects

To initialize the CAN controller, the CPU has to set up the CAN bit timing and those message objects that have to be used for CAN communication. Message objects that are not needed, can be deactivated.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Figure 22-3. CAN Module General Initialization Flow

22.3.1.1.1 Configuration of CAN Bit Timing

The CAN module must be in initialization mode to configure the CAN bit timing.

For CAN bit timing software configuration flow, see Figure 22-4.

Step 1: Enter *initialization mode* by setting the Init (Initialization) bit in the CAN control register.

While the Init bit is set, the message transfer from and to the CAN bus is stopped, and the status of the CAN_TX output is recessive (high).

The CAN error counters are not updated. Setting the Init bit does not change any other configuration register.

Also, note that the CAN module is in initialization mode on hardware reset and during Bus-Off.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Figure 22-4. CAN Bit-Timing Configuration

Step 2: Set the Configure Change Enable (CCE) bit in the CAN control register.

The access to the Bit Timing register (BTR) for the configuration of the bit timing is enabled when both Init and CCE bits in the CAN Control register are set.

Step 3: Wait for the Init bit to get set. This would make sure that the module has entered *Initialization mode*.

Step 4: Write the bit timing values into the bit timing register. See Section 22.3.9.2 for the BTR value calculation for a given bit timing.

Step 5: Clear the CCE and Init bit.

Step 6: Wait for the Init bit to clear. This would ensure that the module has come out of *initialization mode*.

Following these steps, the module comes to operation by synchronizing itself to the CAN bus, provided the BTR is configured as per the CAN bus baud rate, although the message objects have to be configured before carrying out any communication.

NOTE: The module will not come out of the *initialization mode* if any incorrect BTR values are written in step 4.

NOTE: The required message objects should be configured as transmit or receive objects before the start of data transfer as explained in Section 22.3.1.1.

22.3.1.1.2 Configuration of Message Objects

The message objects can be configured only through the interface registers; the CPU does not have direct access to the message object (message RAM) . Familiarize yourself with the interface register set (IFx) usage (see Section 22.3.10) and the message object structure (see Section 22.3.11) before configuring the message objects.

For more information regarding the procedure to configure the message objects, see Section 22.3.7. All the message objects should be configured to particular identifiers or set to not valid before the message transfer is started. It is possible to change the configuration of message objects during normal operation (that is between data transfers).

NOTE: The message objects initialization is independent of the bit-timing configuration.

22.3.1.1.3 DCAN RAM Hardware Initialization

The memory hardware initialization for the DCAN module is enabled in the device control register, DCAN_RAMINIT, which initializes the RAM with zeros and sets parity bits accordingly. Wait for the RAMINIT_DONE bit to be set to ensure successful RAM initialization.

For more details on RAM hardware initialization, see the system module reference guide.

22.3.1.2 CAN Message Transfer (Normal Operation)

Once the DCAN is initialized and Init bit is reset to zero, the CAN core synchronizes itself to the CAN bus and is ready for message transfer as per the configured message objects.

The CPU may enable the interrupt lines (setting IE0 and IE1 to ‘1’) at the same time when it clears Init and CCE. The status interrupts EIE and SIE may be enabled simultaneously.

The CAN communication can be carried out in any of the following two modes: interrupt and polling.

The interrupt register points to those message objects with IntPnd = ‘1’. It is updated even if the interrupt lines to the CPU are disabled (IE0/IE1 are zero).

The CPU may poll all MessageObject’s NewDat and TxRqst bits in parallel from the NewData X registers and the Transmission Request X Registers (DCAN TXRQ X). Polling can be made easier if all transmit objects are grouped at the low numbers and all receive objects are grouped at the high numbers.

Received messages are stored into their appropriate message objects if they pass acceptance filtering.

The whole message (including all arbitration bits, DLC and up to eight data bytes) is stored into the message object. As a consequence (e.g., when the identifier mask is used), the arbitration bits which are masked to “don’t care” may change in the message object when a received message is stored.

The CPU may read or write each message at any time via the interface registers, as the message handler guarantees data consistency in case of concurrent accesses.

If a permanent message object (arbitration and control bits set up during configuration and leaving unchanged for multiple CAN transfers) exists for the message, it is possible to only update the data bytes.

If several transmit messages should be assigned to one message object, the whole message object has to be configured before the transmission of this message is requested.

The transmission of multiple message objects may be requested at the same time. They are subsequently transmitted, according to their internal priority.

Messages may be updated or set to not valid at any time, even if a requested transmission is still pending. However, the data bytes will be discarded if a message is updated before a pending transmission has started.

Depending on the configuration of the message object, a transmission may be automatically requested by the reception of a remote frame with a matching identifier.

22.3.1.2.1 Automatic Retransmission

According to the CAN Specification (ISO11898), the DCAN provides a mechanism to automatically retransmit frames which have lost arbitration or have been disturbed by errors during transmission. The frame transmission service will not be confirmed to the user before the transmission is successfully completed.

By default, this automatic retransmission is enabled. It can be disabled by setting bit disable automatic retransmission (DAR) in the CAN Control register. Further details to this mode are provided in Section 22.3.8.3.

22.3.1.2.2 Auto-Bus-On

By default, after the DCAN has entered Bus-Off state, the CPU can start a Bus-Off-Recovery sequence by resetting the Init bit. If this is not done, the module will stay in Bus-Off state.

The DCAN provides an automatic Auto-Bus-On feature which is enabled by bit ABO in the CAN control register. If set, the DCAN will automatically start the Bus-Off-Recovery sequence. The sequence can be delayed by a user-defined number of L3_SLOW_GCLK cycles which can be defined in the Auto-Bus-On Time register (DCAN ABOTR).

NOTE: If the DCAN goes to Bus-Off state due to a massive occurrence of CAN bus errors, it stops all bus activities and automatically sets the Init bit. Once the Init bit has been reset by the CPU or due to the Auto-Bus-On feature, the device will wait for 129 occurrences of bus Idle (equal to 129 * 11 consecutive recessive bits) before resuming normal operation. At the end of the Bus-Off recovery sequence, the error counters will be reset.

22.3.1.3 Test Modes

The DCAN module provides several test modes which are mainly intended for production tests or self test.

For all test modes, the Test bit in the CAN control register needs to be set to one. This enables write access to the test register (DCAN TEST).

22.3.1.3.1 Silent Mode

The silent mode may be used to analyze the traffic on the CAN bus without affecting it by sending dominant bits (e.g., acknowledge bit, overload flag, active error flag). The DCAN is still able to receive valid data frames and valid remote frames, but it will not send any dominant bits. However, these are internally routed to the CAN core.

Figure 22-5 shows the connection of signals CAN_TX and CAN_RX to the CAN core in silent mode. Silent mode can be activated by setting the Silent bit in the Test register to one. In ISO 11898-1, the silent mode is called the bus monitoring mode.

Figure 22-5. CAN Core in Silent Mode

Copyright © 2011, Texas Instruments Incorporated

22.3.1.3.2 Loopback Mode

The loopback mode is mainly intended for hardware self-test functions. In this mode, the CAN core uses internal feedback from Tx output to Rx input. Transmitted messages are treated as received messages, and can be stored into message objects if they pass acceptance filtering. The actual value of the CAN_RX input pin is disregarded by the CAN core. Transmitted messages can still be monitored at the CAN_TX pin.

In order to be independent from external stimulation, the CAN core ignores acknowledge sampled in the acknowledge slot of a data/remote frame.

Figure 22-6 shows the connection of signals CAN_TX and CAN_RX to the CAN core in loopback mode.

Loopback mode can be activated by setting bit LBack in the test register to one.

NOTE: In loopback mode, the signal path from CAN core to Tx pin, the Tx pin itself, and the signal path from Tx pin back to CAN core are disregarded. For including these into the testing, see Section 22.3.1.3.3.

Figure 22-6. CAN Core in Loopback Mode

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

22.3.1.3.3 External Loopback Mode

The external loopback mode is similar to the loopback mode; however, it includes the signal path from CAN core to Tx pin, the Tx pin itself, and the signal path from Tx pin back to CAN core. When external loopback mode is selected, the input of the CAN core is connected to the input buffer of the Tx pin.

With this configuration, the Tx pin IO circuit can be tested.

External loopback mode can be activated by setting bit **ExL** in test register to one.

Figure 22-7 shows the connection of signals CAN_TX and CAN_RX to the CAN core in external loopback mode.

NOTE: When loopback mode is active (LBack bit set), the ExL bit will be ignored.

Figure 22-7. CAN Core in External Loopback Mode

22.3.1.3.4 Loopback Mode Combined With Silent Mode

It is also possible to combine loopback mode and silent mode by setting bits LBack and Silent at the same time. This mode can be used for a “Hot Selftest,” i.e., the DCAN hardware can be tested without affecting the CAN network. In this mode, the CAN_RX pin is disconnected from the CAN core and no dominant bits will be sent on the CAN_TX pin.

Figure 22-8 shows the connection of the signals CAN_TX and CAN_RX to the CAN core in case of the combination of loopback mode with silent mode.

Copyright © 2011, Texas Instruments Incorporated

Figure 22-8. CAN Core in Loop Back Combined With Silent Mode

22.3.1.3.5 Software Control of CAN_TX pin

Four output functions are available for the CAN transmit pin CAN_TX. In addition to its default function (serial data output), the CAN_TX pin can drive constant dominant or recessive values, or it can drive the CAN sample point signal to monitor the CAN core's bit timing.

Combined with the readable value of the CAN_RX pin, this function can be used to check the physical layer of the CAN bus.

The output mode of pin CAN_TX is selected by programming the test register bits Tx[1:0] as described in section Section 22.5.6.

NOTE: The software control for the CAN_TX pin interferes with CAN protocol functions. For CAN message transfer or any of the test modes (loopback mode, external loopback mode or silent mode), the CAN_TX pin should operate in its default functionality.

22.3.2 Dual Clock Source

Two clock domains are provided to the DCAN module: the peripheral synchronous clock domain (L3_SLOW_GCLK) as the general module clock source, and the peripheral asynchronous clock source domain (OSC0) provided to the CAN core (as clock source CAN_CLK) for generating the CAN bit timing.

Both clock domains can be derived from the same clock source (so that L3_SLOW_GCLK = OSC0).

For more information on how to configure the relevant clock source registers in the system module, see the system module reference guide and the device-specific data sheet.

Between the two clock domains, a synchronization mechanism is implemented in the DCAN module in order to ensure correct data transfer.

NOTE: If the dual clock functionality is used, then L3_SLOW_GCLK must always be higher or equal to CAN_CLK (OSC0) (derived from the asynchronous clock source), in order to achieve a stable functionality of the DCAN. Here also the frequency shift of the modulated L3_SLOW_GCLK has to be considered:

$f_{0,\ L3_SLOW_GCLK}(OCP) \pm \Delta f_{FM,\ L3_SLOW_GCLK}(OCP) \geq f_{CANCLK}$

NOTE: The CAN core has to be programmed to at least 8 clock cycles per bit time. To achieve a transfer rate of 1 MBaud when using the asynchronous clock domain as the clock source for CAN_CLK (OSC0), an oscillator frequency of 8MHz or higher has to be used.

22.3.3 Interrupt Functionality

Interrupts can be generated on two interrupt lines: DCANINT0 and DCANINT1. These lines can be enabled by setting the IE0 and IE1 bits, respectively, in the CAN control register. The interrupts are level triggered at the chip level.

The DCAN provides three groups of interrupt sources: message object interrupts, status change interrupts, and error interrupts (see Figure 22-9 and Figure 22-10).

The source of an interrupt can be determined by the interrupt identifiers Int0ID/Int1ID in the interrupt register (see Section 22.5.5). When no interrupt is pending, the register will hold the value zero.

Each interrupt line remains active until the dedicated field in the interrupt register DCAN INT (Int0ID / Int1ID) again reach zero (this means the cause of the interrupt is reset), or until IE0 / IE1 are reset.

The value 0x8000 in the Int0ID field indicates that an interrupt is pending because the CAN core has updated (not necessarily changed) the Error and Status register (DCAN ES and PARITYERR_EOI). This interrupt has the highest priority. The CPU can update (reset) the status bits WakeUpPnd, RxOk, TxOk and LEC by reading the error and status register DCAN ES, but a write access of the CPU will never generate or reset an interrupt.

Values between 1 and the number of the last message object indicates that the source of the interrupt is one of the message objects, Int0ID resp. Int1ID will point to the pending message interrupt with the highest priority. The Message Object 1 has the highest priority; the last message object has the lowest priority.

An interrupt service routine that reads the message that is the source of the interrupt may read the message and reset the message object's IntPnd at the same time (ClrIntPnd bit in the IF1/IF2 command register). When IntPnd is cleared, the interrupt register will point to the next message object with a pending interrupt.

22.3.3.1 Message Object Interrupts

Message object interrupts are generated by events from the message objects. They are controlled by the flags IntPND, TxIE and RxIE that are described in Section 22.3.11.1.

Message object interrupts can be routed to either DCANINT0 or DCANINT1 line, controlled by the interrupt multiplexer register (DCAN INTMUX12 to DCAN INTMUX78), see Section 22.5.17.

22.3.3.2 Status Change Interrupts

The events WakeUpPnd, RxOk, TxOk and LEC in error and status register (DCAN ES) belong to the status change interrupts. The status change interrupt group can be enabled by bit in CAN control register.

If SIE is set, a status change interrupt will be generated at each CAN frame, independent of bus errors or valid CAN communication, and also independent of the message RAM configuration.

Status change interrupts can only be routed to interrupt line DCAN0INT, which has to be enabled by setting IE0 in the CAN control register.

NOTE: Reading the error and status register will clear the WakeUpPnd flag. If in global power-down mode, the WakeUpPnd flag is cleared by such a read access before the DCAN module has been waken up by the system, the DCAN may re-assert the WakeUpPnd flag, and a second interrupt may occur.

22.3.3.3 Error Interrupts

The events PER, BOff and EWarn, monitored in the Error and Status register, DCAN ES, belong to the error interrupts. The error interrupt group can be enabled by setting bit EIE in the CAN Control register.

Error interrupts can only be routed to interrupt line DCAN0INT, which has to be enabled by setting IE0 in the CAN Control register.

22.3.4 Local Power-Down Mode

The DCAN supports a local power-down mode, which can be controlled within the DCAN control registers.

22.3.4.1 Entering Local Power-Down Mode

The local power-down mode is requested by setting the PDR bit in CAN Control register.

The DCAN then finishes all transmit requests of the message objects. When all requests are done, DCAN waits until a bus idle state is recognized. Then it will automatically set the Init bit in CAN control register to prevent any further CAN transfers, and it will also set the PDA bit in CAN error and status register. With setting the PDA bits, the DCAN module indicates that the local power-down mode has been entered.

During local power-down mode, the internal clocks of the DCAN module are turned off, but there is a wakeup logic (see Section 22.3.4.2) that can be active, if enabled. Also, the actual contents of the control registers can be read back.

NOTE: In local low-power mode, the application should not clear the Init bit while PDR is set. If there are any messages in the message RAM which are configured as transmit messages and the application resets the init bit, these messages may get sent.

22.3.4.2 Wakeup From Local Power Down

There are two ways to wake up the DCAN from local power-down mode:

- The application could wake up the DCAN module manually by clearing the PDR bit and then clearing the Init bit in CAN Control register.
- Alternatively, a CAN bus activity detection circuit can be activated by setting the wakeup on bus activity bit (WUBA) in the CAN control register. If this circuit is active, on occurrence of a dominant CAN bus level, the DCAN will automatically start the wakeup sequence. It will clear the PDR bit in the CAN Control register and also clear the PDA bit in the error and status register. The WakeUpPnd bit in CAN error and status register will be set. If status interrupts are enabled, also an interrupt will be generated. Finally the Init bit in CAN control register will be cleared.

After the Init bit has been cleared, the module waits until it detects 11 consecutive recessive bits on the CAN_RX pin and then goes bus-active again.

NOTE: The CAN transceiver circuit has to stay active in order to detect any CAN bus activity while the DCAN is in local power down mode. The first CAN message, which initiates the bus activity, cannot be received. This means that the first message received in power-down and automatic wake-up mode, is lost.

Figure 22-11 shows a flow diagram about entering and leaving local power-down mode.

22.3.5 Parity Check Mechanism

The DCAN provides a parity check mechanism to ensure data integrity of message RAM data. For each word (32 bits) in message RAM, one parity bit will be calculated. The formation of the different words is according to the message RAM representation in RDA mode, see Section 22.3.11.4.

Parity information is stored in the message RAM on write accesses and will be checked against the stored parity bit from message RAM on read accesses.

The Parity check functionality can be enabled or disabled by PMD bit field in the CAN control register.

In case of disabled parity check, the parity bits in message RAM will be left unchanged on write access to data area and no check will be done on read access.

If parity checking is enabled, parity bits will be automatically generated and checked by the DCAN. The parity bits could be read in debug/suspend mode (see Section 22.3.11.3) or in RDA mode (see Section 22.3.11.4). However, direct write access to the parity bits is only possible in this two modes with parity check disabled.

A parity bit will be set, if the modulo-2-sum of the data bits is 1. This definition is equivalent to: The parity bit will be set, if the number of 1 bits in the data is odd.

NOTE: The parity scheme is tied to even parity at the device level.

22.3.5.1 Behavior on Parity Error

On any read access to message RAM (e.g., during start of a CAN frame transmission), the parity of the message object will be checked. If a parity error is detected, the PER bit in the error and status register will be set. If error interrupts are enabled, an interrupt would also be generated. In order to avoid the transmission of invalid data over the CAN bus, the d bit of the message object will be reset.

The message object data can be read by the host CPU, independently of parity errors. Thus, the application has to ensure that the read data is valid, e.g., by immediately checking the parity error code register (DCAN PERR) on parity error interrupt.

NOTE: During RAM initialization, no parity check will be done.

22.3.5.2 Parity Testing

Testing the parity mechanism can be done by enabling the bit RamDirectAccess (RDA) and manually writing the parity bits directly to the dedicated RAM locations. With this, data and parity bits could be checked when reading directly from RAM.

NOTE: If parity check was disabled, the application has to ensure correct parity bit handling in order to prevent parity errors later on when parity check is enabled.

DRAFT ONLY

22.3.6 Debug/Suspend Mode

The module supports the usage of an external debug unit by providing functions like pausing DCAN activities and making message RAM content accessible via OCP interface.

Before entering debug/suspend mode, the circuit will either wait until a started transmission or reception will be finished and bus idle state is recognized, or immediately interrupt a current transmission or reception. This is depending on bit IDS in the CAN control register.

Afterwards, the DCAN enters debug/suspend mode, indicated by InitDbg flag in the CAN control register.

During debug/suspend mode, all DCAN registers can be accessed. Reading reserved bits will return ‘0’. Writing to reserved bits will have no effect.

Also, the message RAM will be memory mapped. This allows the external debug unit to read the message RAM. For the memory organization, see Section 22.3.11.3).

NOTE: During debug/suspend mode, the message RAM cannot be accessed via the IFx register sets.

NOTE: Writing to control registers in debug/suspend mode may influence the CAN state machine and further message handling.

For debug support, the auto clear functionality of the following DCAN registers is disabled:

- Error and status register (clear of status flags by read)
- IF1/IF2 command registers (clear of DMAActive flag by read/write)

22.3.7 Configuration of Message Objects

The whole message RAM should be configured before the end of the initialization, however it is also possible to change the configuration of message objects during CAN communication.

The CAN software driver library should offer subroutines that:

- Transfer a complete message structure into a message object. (Configuration)
- Transfer the data bytes of a message into a message object and set TxRqst and NewDat. (Start a new transmission)
- Get the data bytes of a message from a message object and clear NewDat (and IntPnd). (Read received data)
- Get the complete message from a message object and clear NewDat (and IntPnd). (Read a received message, including identifier, from a message object with UMask = ‘1’)

Parameters of the subroutines are the Message Number and a pointer to a complete message structure or to the data bytes of a message structure.

Two examples of assigning the IFx interface register sets to these subroutines are shown here:

In the first method, the tasks of the application program that may access the module are divided into two groups. Each group is restricted to the use of one of the interface register sets. The tasks of one group may interrupt tasks of the other group, but not of the same group.

In the second method, which may be a special case of the first method, there are only two tasks in the application program that access the module. A Read_Message task that uses IF2 or IF3 to get received messages from the message RAM and a Write_Message task that uses IF1 to write messages to be transmitted (or to be configured) into the message RAM. Both tasks may interrupt each other.

22.3.7.1 Configuration of a Transmit Object for Data Frames

Table 22-4 shows how a transmit object can be initialized.

Table 22-4. Initialization of a Transmit Object

MsgVal	Arb	Data	Mask	EoB	Dir	NewDat	MsgLst	RxIE	TxIE	IntPnd	RmtEn	TxRqst
1	appl.	appl.	appl.	1	1	0	0	0	appl.	0	appl.	0

The arbitration bits (ID[28:0] and Xtd bit) are given by the application. They define the identifier and type of the outgoing message. If an 11-bit identifier (standard frame) is used (Xtd = ‘0’), it is programmed to ID[28:18]. In this case, ID[17:0] can be ignored.

The data registers (DLC[3:0] and Data0-7) are given by the application. TxRqst and RmtEn should not be set before the data is valid.

If the TxIE bit is set, the IntPnd bit will be set after a successful transmission of the message object.

If the RmtEn bit is set, a matching received remote frame will cause the TxRqst bit to be set; the remote frame will autonomously be answered by a data frame.

The mask bits (Msk[28:0], UMask, MXtd, and MDir bits) may be used (UMask=’1’) to allow groups of remote frames with similar identifiers to set the TxRqst bit. The Dir bit should not be masked. For details, see Section 22.3.8.8. Identifier masking must be disabled (UMask = ‘0’) if no remote frames are allowed to set the TxRqst bit (RmtEn = ‘0’).

22.3.7.2 Configuration of a Transmit Object for Remote Frames

It is not necessary to configure transmit objects for the transmission of remote frames. Setting TxRqst for a receive object causes the transmission of a remote frame with the same identifier as the data rrame for which this receive object is configured.

22.3.7.3 Configuration of a Single Receive Object for Data Frames

Table 22-5 shows how a receive object for data frames can be initialized.

Table 22-5. Initialization of a single Receive Object for Data Frames

MsgVal	Arb	Data	Mask	EoB	Dir	NewDat	MsgLst	RxIE	TxIE	IntPnd	RmtEn	TxRqst
1	appl.	appl.	appl.	1	0	0	0	appl.	0	0	0	0

The arbitration bits (ID[28:0] and Xtd bit) are given by the application. They define the identifier and type of accepted received messages. If an 11-bit Identifier (standard frame) is used (Xtd = ‘0’), it is programmed to ID[28:18]. In this case, ID[17:0] can be ignored. When a data frame with an 11-bit Identifier is received, ID[17:0] is set to ‘0’.

The data length code (DLC[3:0]) is given by the application. When the message handler stores a data frame in the message object, it will store the received data length code and eight data bytes. If the data length code is less than 8, the remaining bytes of the message object may be overwritten by non specified values.

The mask bits (Msk[28:0], UMask, MXtd, and MDir bits) may be used (UMask = ’1’) to allow groups of data frames with similar identifiers to be accepted. The Dir bit should not be masked in typical applications. If some bits of the mask bits are set to “don’t care,” the corresponding bits of the arbitration register will be overwritten by the bits of the stored data frame.

If the RxIE bit is set, the IntPnd bit will be set when a received data frame is accepted and stored in the message object.

If the TxRqst bit is set, the transmission of a remote frame with the same identifier as actually stored in the arbitration bits will be triggered. The content of the arbitration bits may change if the mask bits are used (UMask = ’1’) for acceptance filtering.

Copyright © 2011, Texas Instruments Incorporated

22.3.7.4 Configuration of a Single Receive Object for Remote Frames

Table 22-6 shows how a receive object for remote frames can be initialized.

Table 22-6. Initialization of a Single Receive Object for Remote Frames

MsgVal	Arb	Data	Mask	EoB	Dir	NewDat	MsgLst	RxIE	TxIE	IntPnd	RmtEn	TxRqst
1	appl.	appl.	appl.	1	1	0	0	appl.	0	0	0	0

A receive object for remote frames may be used to monitor remote frames on the CAN bus. The remote frame stored in the receive object will not trigger the transmission of a data frame. Receive objects for remote frames may be expanded to a FIFO buffer (see Section 22.3.7.5).

UMask must be set to ‘1.’ The mask bits (Msk[28:0], UMask, MXtd, and MDir bits) may be set to “must-match” or to “don’t care,” to allow groups of remote frames with similar identifiers to be accepted. The Dir bit should not be masked in typical applications. For details, see Section 22.3.8.8.

The arbitration bits (ID[28:0] and Xtd bit) may be given by the application. They define the identifier and type of accepted received remote frames. If some bits of the mask bits are set to “don’t care,” the corresponding bits of the arbitration bits will be overwritten by the bits of the stored remote frame. If an 11-bit Identifier (standard frame) is used (Xtd = ‘0’), it is programmed to ID[28:18]. In this case, ID[17:0] can be ignored. When a remote frame with an 11-bit Identifier is received, ID[17:0] will be set to ‘0.’

The data length code (DLC[3:0]) may be given by the application. When the message handler stores a remote frame in the message object, it will store the received data length code. The data bytes of the message object will remain unchanged.

If the RxIE bit is set, the IntPnd bit will be set when a received remote frame is accepted and stored in the message object.

22.3.7.5 Configuration of a FIFO Buffer

With the exception of the EoB bit, the configuration of receive objects belonging to a FIFO buffer is the same as the configuration of a single receive object.

To concatenate multiple message objects to a FIFO buffer, the identifiers and masks (if used) of these message objects have to be programmed to matching values. Due to the implicit priority of the message objects, the message object with the lowest number will be the first message object of the FIFO buffer. The EoB bit of all message objects of a FIFO buffer except the last one have to be programmed to zero. The EoB bits of the last message object of a FIFO Buffer is set to one, configuring it as the end of the block.

22.3.8 Message Handling

When initialization is finished, the DCAN module synchronizes itself to the traffic on the CAN bus. It does acceptance filtering on received messages and stores those frames that are accepted into the designated message objects. The application has to update the data of the messages to be transmitted and to enable and request their transmission. The transmission is requested automatically when a matching remote frame is received.

The application may read messages which are received and accepted. Messages that are not read before the next messages is accepted for the same message object will be overwritten.

Messages may be read interrupt-driven or after polling of NewDat.

22.3.8.1 Message Handler Overview

The message handler state machine controls the data transfer between the Rx/Tx shift register of the CAN core and the message RAM. It performs the following tasks:

- Data transfer from message RAM to CAN core (messages to be transmitted)
- Data transfer from CAN core to the message RAM (received messages)
- Data transfer from CAN core to the acceptance filtering unit
- Scanning of message RAM for a matching message object (acceptance filtering)
- Scanning the same message object after being changed by IF1/IF2 registers when priority is the same or higher as the message the object found by last scanning
- Handling of TxRqst flags
- Handling of interrupt flags

The message handler registers contains status flags of all message objects grouped into the following topics:

- Transmission Request Flags
- New Data Flags
- Interrupt Pending Flags
- Message Valid Registers

Instead of collecting above listed status information of each message object via IFx registers separately, these message handler registers provides a fast and easy way to get an overview, for example, about all pending transmission requests.

All message handler registers are read-only.

22.3.8.2 Receive/Transmit Priority

The receive/transmit priority for the message objects is attached to the message number, not to the CAN identifier. Message object 1 has the highest priority, while the last implemented message object has the lowest priority. If more than one transmission request is pending, they are serviced due to the priority of the corresponding message object so messages with the highest priority, for example, can be placed in the message objects with the lowest numbers.

The acceptance filtering for received data frames or remote frames is also done in ascending order of message objects, so a frame that has been accepted by a message object cannot be accepted by another message object with a higher message number. The last message object may be configured to accept any data frame or remote frame that was not accepted by any other message object, for nodes that need to log the complete message traffic on the CAN bus.

22.3.8.3 Transmission of Messages in Event Driven CAN Communication

If the shift register of the CAN core is ready for loading and if there is no data transfer between the IFx registers and message RAM, the d bits in the Message Valid register (DCAN MSGVAL12 to DCAN MSGVAL78) and the TxRqst bits in the transmission request register are evaluated. The valid message object with the highest priority pending transmission request is loaded into the shift register by the message handler and the transmission is started. The message object's NewDat bit is reset.

Copyright © 2011, Texas Instruments Incorporated

After a successful transmission and if no new data was written to the message object (NewDat = ‘0’) since the start of the transmission, the TxRqst bit will be reset. If TxIE is set, IntPnd will be set after a successful transmission. If the DCAN has lost the arbitration or if an error occurred during the transmission, the message will be retransmitted as soon as the CAN bus is free again. If meanwhile the transmission of a message with higher priority has been requested, the messages will be transmitted in the order of their priority.

If automatic retransmission mode is disabled by setting the DAR bit in the CAN control register, the behavior of bits TxRqst and NewDat in the Message Control register of the interface register set is as follows:

- When a transmission starts, the TxRqst bit of the respective interface register set is reset, while bit NewDat remains set.
- When the transmission has been successfully completed, the NewDat bit is reset.

When a transmission failed (lost arbitration or error) bit NewDat remains set. To restart the transmission, the application has to set TxRqst again.

Received remote frames do not require a receive object. They will automatically trigger the transmission of a data frame, if in the matching transmit object the RmtEn bit is set.

22.3.8.4 Updating a Transmit Object

The CPU may update the data bytes of a transmit object any time via the IF1/IF2 interface registers, neither d nor TxRqst have to be reset before the update.

Even if only a part of the data bytes are to be updated, all four bytes in the corresponding IF1/IF2 Data A register (DCAN IF1DATA/DCAN IF2DATA) or IF1/IF2 Data B register (DCAN IF1DATB/DCAN IF2DATB) have to be valid before the content of that register is transferred to the message object. Either the CPU has to write all four bytes into the IF1/IF2 data register or the message object is transferred to the IF1/IF2 data register before the CPU writes the new data bytes.

When only the data bytes are updated, first 0x87 can be written to bits [23:16] of the IF1/IF2 Command register (DCAN IF1CMD/DCAN IF2CMD) and then the number of the message object is written to bits [7:0] of the command register, concurrently updating the data bytes and setting TxRqst with NewDat.

To prevent the reset of TxRqst at the end of a transmission that may already be in progress while the data is updated, NewDat has to be set together with TxRqst in event driven CAN communication. For details, see Section 22.3.8.3.

When NewDat is set together with TxRqst, NewDat will be reset as soon as the new transmission has started.

22.3.8.5 Changing a Transmit Object

If the number of implemented message objects is not sufficient to be used as permanent message objects only, the transmit objects may be managed dynamically. The CPU can write the whole message (arbitration, control, and data) into the interface register. The bits [23:16] of the command register can be set to 0xB7 for the transfer of the whole message object content into the message object. Neither d nor TxRqst have to be reset before this operation.

If a previously requested transmission of this message object is not completed but already in progress, it will be continued; however, it will not be repeated if it is disturbed.

To only update the data bytes of a message to be transmitted, bits [23:16] of the command register should be set to 0x87.

NOTE: After the update of the transmit object, the interface register set will contain a copy of the actual contents of the object, including the part that had not been updated.

22.3.8.6 Acceptance Filtering of Received Messages

When the arbitration and control bits (Identifier + IDE + RTR + DLC) of an incoming message are completely shifted into the shift register of the CAN core, the message handler starts the scan of the message RAM for a matching valid message object:

- The acceptance filtering unit is loaded with the arbitration bits from the CAN core shift register.
- Then the arbitration and mask bits (including MsgVal, UMask, NewDat, and EoB) of message object 1 are loaded into the acceptance filtering unit and are compared with the arbitration bits from the shift register. This is repeated for all following message objects until a matching message object is found, or until the end of the message RAM is reached.
- If a match occurs, the scanning is stopped and the message handler proceeds depending on the type of the frame (data frame or remote frame) received.

22.3.8.7 Reception of Data Frames

The message handler stores the message from the CAN core shift register into the respective message object in the message RAM. Not only the data bytes, but all arbitration bits and the data length code are stored into the corresponding message object. This ensures that the data bytes stay associated to the identifier even if arbitration mask registers are used.

The NewDat bit is set to indicate that new data (not yet seen by the CPU) has been received. The CPU should reset the NewDat bit when it reads the message object. If at the time of the reception the NewDat bit was already set, MsgLst is set to indicate that the previous data (supposedly not seen by the CPU) is lost. If the RxIE bit is set, the IntPnd bit is set, causing the interrupt register to point to this message object.

The TxRqst bit of this message object is reset to prevent the transmission of a remote frame, while the requested data frame has just been received.

22.3.8.8 Reception of Remote Frames

When a remote frame is received, three different configurations of the matching message object have to be considered:

- Dir = ‘1’ (direction = transmit), RmtEn = ‘1’, UMask = ‘1’ or ‘0’

  The TxRqst bit of this message object is set at the reception of a matching remote frame. The rest of the message object remains unchanged.
- Dir = ‘1’ (direction = transmit), RmtEn = ‘0’, UMask = ‘0’

  The remote frame is ignored, this message object remains unchanged.
- Dir = ‘1’ (direction = transmit), RmtEn = ‘0’, UMask = ‘1’

  The remote frame is treated similar to a received data frame. At the reception of a matching Remote Message Handling October 2009 Controller Area Network (DCAN) Module 371 www.ti.com Frame, the TxRqst bit of this message object is reset. The arbitration and control bits (Identifier + IDE + RTR + DLC) from the shift register are stored in the message object in the message RAM and the NewDat bit of this message object is set. The data bytes of the message object remain unchanged.

22.3.8.9 Reading Received Messages

The CPU may read a received message any time via the IFx interface register. The data consistency is guaranteed by the message handler state machine. Typically the CPU will write first 0x7F to bits [23:16] and then the number of the message object to bits [7:0] of the command register. That combination will transfer the entire received message from the message RAM into the interface register set. Additionally, the bits NewDat and IntPnd are cleared in the message RAM (not in the interface register set). The values of these bits in the message control register always reflect the status before resetting the bits. If the message object uses masks for acceptance filtering, the arbitration bits show which of the different matching messages has been received.

The actual value of NewDat shows whether a new message has been received since last time when this message object was read. The actual value of MsgLst shows whether more than one message has been received since the last time when this message object was read. MsgLst will not be automatically reset.

Copyright © 2011, Texas Instruments Incorporated

22.3.8.10 Requesting New Data for a Receive Object

By means of a remote frame, the CPU may request another CAN node to provide new data for a receive object. Setting the TxRqst bit of a receive object will cause the transmission of a remote frame with the identifier of the receive object. This remote frame triggers the other CAN node to start the transmission of the matching data frame. If the matching data frame is received before the remote frame could be transmitted, the TxRqst bit is automatically reset. Setting the TxRqst bit without changing the contents of a message object requires the value 0x84 in bits [23:16] of the command register.

22.3.8.11 Storing Received Messages in FIFO Buffers

Several message objects may be grouped to form one or more FIFO buffers. Each FIFO buffer configured to store received messages with a particular (group of) identifier(s). arbitration and mask registers of the FIFO buffer's message objects are identical. The end of buffer (EoB) bits of all but the last of the FIFO buffer's message objects are '0'; in the last one the EoB bit is '1.'

Received messages with identifiers matching to a FIFO buffer are stored into a message object of this FIFO buffer, starting with the message object with the lowest message number. When a message is stored into a message object of a FIFO buffer, the NewDat bit of this message object is set. By setting NewDat while EoB is '0', the message object is locked for further write accesses by the message handler until the CPU has cleared the NewDat bit.

Messages are stored into a FIFO buffer until the last message object of this FIFO buffer is reached. If none of the preceding message objects is released by writing NewDat to '0,' all further messages for this FIFO buffer will be written into the last message object of the FIFO buffer (EoB = '1') and therefore overwrite previous messages in this message object.

22.3.8.12 Reading From a FIFO Buffer

Several messages may be accumulated in a set of message objects which are concatenated to form a FIFO buffer before the application program is required (in order to avoid the loss of data) to empty the buffer.

A FIFO buffer of length N will store –1 plus the last received message since last time it was cleared.

A FIFO buffer is cleared by reading and resetting the NewDat bits of all its message objects, starting at the FIFO Object with the lowest message number. This should be done in a subroutine following the example shown in Figure 22-12.

NOTE: All message objects of a FIFO buffer needs to be read and cleared before the next batch of messages can be stored. Otherwise, true FIFO functionality can not be guaranteed, since the message objects of a partly read buffer will be re-filled according to the normal (descending) priority.

Reading from a FIFO buffer message object and resetting its NewDat bit is handled the same way as reading from a single message object.

22.3.9 CAN Bit Timing

The DCAN supports bit rates between less than 1 kBit/s and 1000 kBit/s.

Each member of the CAN network has its own clock generator, typically derived from a crystal oscillator. The bit timing parameters can be configured individually for each CAN node, creating a common bit rate even though the CAN nodes' oscillator periods (f_{osc}) may be different.

The frequencies of these oscillators are not absolutely stable. Small variations are caused by changes in temperature or voltage and by deteriorating components. As long as the variations remain inside a specific oscillator tolerance range (df), the CAN nodes are able to compensate for the different bit rates by resynchronizing to the bit stream.

In many cases, the CAN bit synchronization will amend a faulty configuration of the CAN bit timing to such a degree that only occasionally an error frame is generated. In the case of arbitration however, when two or more CAN nodes simultaneously try to transmit a frame, a misplaced sample point may cause one of the transmitters to become error passive.

The analysis of such sporadic errors requires a detailed knowledge of the CAN bit synchronization inside a CAN node and of the CAN nodes' interaction on the CAN bus.

Even if minor errors in the configuration of the CAN bit timing do not result in immediate failure, the performance of a CAN network can be reduced significantly.

22.3.9.1 Bit Time and Bit Rate

According to the CAN specification, the bit time is divided into four segments (see Figure 22-13):

- Synchronization segment (Sync_Seg)
- Propagation time segment (Prop_Seg)
- Phase buffer segment 1 (Phase_Seg1)
- Phase buffer segment 2 (Phase_Seg2)

Figure 22-13. Bit Timing

Each segment consists of a specific number of time quanta. The length of one time quantum (t_q), which is the basic time unit of the bit time, is given by the CAN_CLK and the baud rate prescalers (BRPE and BRP). With these two baud rate prescalers combined, divider values from 1 to 1024 can be programmed:

t_q = Baud Rate Prescaler / CAN_CLK

Apart from the fixed length of the synchronization segment, these numbers are programmable. Table 22-7 describes the minimum programmable ranges required by the CAN protocol.

A given bit rate may be met by different bit time configurations.

Table 22-7. Parameters of the CAN Bit Time

Parameter	Range	Remark
Sync_Seg	1 t_q (fixed)	Synchronization of bus input to CAN_CLK
Prop_Seg	[1 … 8] t_q	Compensates for the physical delay times
Phase_Seg1	[1 … 8] t_q	May be lengthened temporarily by synchronization
Phase_Seg2	[1 … 8] t_q	May be shortened temporarily by synchronization
Synchronization Jump Width (SJW)	[1 … 4] t_q	May not be longer than either Phase Buffer Segment

NOTE: For proper functionality of the CAN network, the physical delay times and the oscillator's tolerance range have to be considered.

22.3.9.1.1 Synchronization Segment

The synchronization segment (Sync_Seg) is the part of the bit time where edges of the CAN bus level are expected to occur. If an edge occurs outside of Sync_Seg, its distance to the Sync_Seg is called the phase error of this edge.

22.3.9.1.2 Propagation Time Segment

This part of the bit time is used to compensate physical delay times within the CAN network. These delay times consist of the signal propagation time on the bus and the internal delay time of the CAN nodes.

Any CAN node synchronized to the bit stream on the CAN bus can be out of phase with the transmitter of the bit stream, caused by the signal propagation time between the two nodes. The CAN protocol's nondestructive bitwise arbitration and the dominant acknowledge bit provided by receivers of CAN messages require that a CAN node transmitting a bit stream must also be able to receive dominant bits transmitted by other CAN nodes that are synchronized to that bit stream. The example in Figure 22-14 shows the phase shift and propagation times between two CAN nodes.

Figure 22-14. The Propagation Time Segment

Delay A_to_B >= node output delay(A) + bus line delay(A→B) + node input delay(B)

Prop_Seg >= Delay A_to_B + Delay B_to_A

Prop_Seg >= 2 • [max(node output delay+bus line delay + node input delay)]

In this example, both nodes A and B are transmitters performing an arbitration for the CAN bus. The node A has sent its start of frame bit less than one bit time earlier than node B, therefore node B has

Copyright © 2011, Texas Instruments Incorporated

synchronized itself to the received edge from recessive to dominant. Since node B has received this edge delay(A_to_B) after it has been transmitted, node B's bit timing segments are shifted with regard to node A. Node B sends an identifier with higher priority and so it will win the arbitration at a specific identifier bit when it transmits a dominant bit while node A transmits a recessive bit. The dominant bit transmitted by node B will arrive at node A after the delay (B_to_A).

Due to oscillator tolerances, the actual position of node A's sample point can be anywhere inside the nominal range of node A's Phase Buffer Segments, so the bit transmitted by node B must arrive at node A before the start of Phase_Seg1. This condition defines the length of Prop_Seg.

If the edge from recessive to dominant transmitted by node B would arrive at node A after the start of Phase_Seg1, it could happen that node A samples a recessive bit instead of a dominant bit, resulting in a bit error and the destruction of the current frame by an error flag.

This error only occurs when two nodes arbitrate for the CAN bus which have oscillators of opposite ends of the tolerance range and are separated by a long bus line; this is an example of a minor error in the bit timing configuration (Prop_Seg too short) that causes sporadic bus errors.

Some CAN implementations provide an optional 3 Sample Mode. The DCAN does not. In this mode, the CAN bus input signal passes a digital low-pass filter, using three samples and a majority logic to determine the valid bit value. This results in an additional input delay of 1 t_q, requiring a longer Prop_Seg.

22.3.9.1.3 Phase Buffer Segments and Synchronization

The phase buffer segments (Phase_Seg1 and Phase_Seg2) and the synchronization jump width (SJW) are used to compensate for the oscillator tolerance.

The phase buffer segments surround the sample point and may be lengthened or shortened by synchronization.

The synchronization jump width (SJW) defines how far the resynchronizing mechanism may move the sample point inside the limits defined by the phase buffer segments to compensate for edge phase errors.

Synchronizations occur on edges from recessive to dominant. Their purpose is to control the distance between edges and sample points.

Edges are detected by sampling the actual bus level in each time quantum and comparing it with the bus level at the previous sample point. A synchronization may be done only if a recessive bit was sampled at the previous sample point and if the actual time quantum's bus level is dominant.

An edge is synchronous if it occurs inside of Sync_Seg; otherwise, its distance to the Sync_Seg is the edge phase error, measured in time quanta. If the edge occurs before Sync_Seg, the phase error is negative, else it is positive.

Two types of synchronization exist: hard synchronization and resynchronizing. A hard synchronization is done once at the start of a frame; inside a frame, only resynchronization is possible.

- Hard Synchronization

  After a hard synchronization, the bit time is restarted with the end of Sync_Seg, regardless of the edge phase error. Thus hard synchronization forces the edge which has caused the hard synchronization, to lie within the synchronization segment of the restarted bit time.

- Bit Resynchronizations

  Resynchronization leads to a shortening or lengthening of the Bit time such that the position of the sample point is shifted with regard to the edge.

  When the phase error of the edge which causes resynchronization is positive, Phase_Seg1 is lengthened. If the magnitude of the phase error is less than SJW, Phase_Seg1 is lengthened by the magnitude of the phase error, else it is lengthened by SJW.

  When the phase error of the edge which causes Resynchronization is negative, Phase_Seg2 is shortened. If the magnitude of the phase error is less than SJW, Phase_Seg2 is shortened by the magnitude of the phase error, else it is shortened by SJW.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

If the magnitude of the phase error of the edge is less than or equal to the programmed value of SJW, the results of hard synchronization and resynchronization are the same. If the magnitude of the phase error is larger than SJW, the resynchronization cannot compensate the phase error completely, and an error of (phase error - SJW) remains.

Only one synchronization may be done between two sample points. The synchronizations maintain a minimum distance between edges and sample points, giving the bus level time to stabilize and filtering out spikes that are shorter than (Prop_Seg + Phase_Seg1).

Apart from noise spikes, most synchronizations are caused by arbitration. All nodes synchronize “hard” on the edge transmitted by the “leading” transceiver that started transmitting first, but due to propagation delay times, they cannot become ideally synchronized. The leading transmitter does not necessarily win the arbitration; therefore, the receivers have to synchronize themselves to different transmitters that subsequently take the lead and that are differently synchronized to the previously leading transmitter. The same happens at the acknowledge field, where the transmitter and some of the receivers will have to synchronize to that receiver that takes the lead in the transmission of the dominant acknowledge bit.

Synchronizations after the end of the arbitration will be caused by oscillator tolerance, when the differences in the oscillator’s clock periods of transmitter and receivers sum up during the time between synchronizations (at most ten bits). These summarized differences may not be longer than the SJW, limiting the oscillator’s tolerance range.

Figure 22-15 shows how the phase buffer segments are used to compensate for phase errors. There are three drawings of each two consecutive bit timings. The upper drawing shows the synchronization on a “late” edge, the lower drawing shows the synchronization on an “early” edge, and the middle drawing is the reference without synchronization.

Figure 22-15. Synchronization on Late and Early Edges

In the first example, an edge from recessive to dominant occurs at the end of Prop_Seg. The edge is "late" since it occurs after the Sync_Seg. Reacting to the late edge, Phase_Seg1 is lengthened so that the distance from the edge to the sample point is the same as it would have been from the Sync_Seg to the sample point if no edge had occurred. The phase error of this late edge is less than SJW, so it is fully compensated and the edge from dominant to recessive at the end of the bit, which is one nominal bit time long, occurs in the Sync_Seg.

In the second example, an edge from recessive to dominant occurs during Phase_Seg2. The edge is "early" since it occurs before a Sync_Seg. Reacting to the early edge, Phase_Seg2 is shortened and Sync_Seg is omitted, so that the distance from the edge to the sample point is the same as it would have been from a Sync_Seg to the sample point if no edge had occurred. As in the previous example, the magnitude of this early edge’s phase error is less than SJW, so it is fully compensated.

Copyright © 2011, Texas Instruments Incorporated

The phase buffer segments are lengthened or shortened temporarily only; at the next bit time, the segments return to their nominal programmed values.

In these examples, the bit timing is seen from the point of view of the CAN implementation's state machine, where the bit time starts and ends at the sample points. The state machine omits Sync_Seg when synchronizing on an early edge because it cannot subsequently redefine that time quantum of Phase_Seg2 where the edge occurs to be the Sync_Seg.

Figure 22-16 shows how short dominant noise spikes are filtered by synchronizations. In both examples, the spike starts at the end of Prop_Seg and has the length of (Prop_Seg + Phase_Seg1).

In the first example, the synchronization jump width is greater than or equal to the phase error of the spike's edge from recessive to dominant. Therefore the sample point is shifted after the end of the spike; a recessive bus level is sampled.

In the second example, SJW is shorter than the phase error, so the sample point cannot be shifted far enough; the dominant spike is sampled as actual bus level.

Figure 22-16. Filtering of Short Dominant Spikes

22.3.9.1.4 Oscillator Tolerance Range

With the introduction of CAN protocol version 1.2, the option to synchronize on edges from dominant to recessive became obsolete. Only edges from recessive to dominant are considered for synchronization. The protocol update to version 2.0 (A and B) had no influence on the oscillator tolerance.

The tolerance range df for an oscillator's frequency f_{osc} around the nominal frequency f_{nom} with:

$$(1-df)\bullet f_{nom} \le f_{osc} \le (1+df)\bullet f_{nom}$$

depends on the proportions of Phase_Seg1, Phase_Seg2, SJW, and the bit time. The maximum tolerance df is the defined by two conditions (both shall be met):

$$\text{I:} \quad df \le \frac{\min(TSeg1, TSeg2)}{2x(13x(bit_time - TSeg2))}$$

$$\text{II:} \quad df \le \frac{SJW}{20xbit_time}$$

It has to be considered that SJW may not be larger than the smaller of the phase buffer segments and that the propagation time segment limits that part of the bit time that may be used for the phase buffer segments.

Copyright © 2011, Texas Instruments Incorporated

The combination Prop_Seg = 1 and Phase_Seg1 = Phase_Seg2 = SJW = 4 allows the largest possible oscillator tolerance of 1.58%. This combination with a propagation time segment of only 10% of the bit time is not suitable for short bit times; it can be used for bit rates of up to 125 kBit/s (bit time = 8 µs) with a bus length of 40 m.

22.3.9.2 DCAN Bit Timing Registers

In the DCAN, the bit timing configuration is programmed in two register bytes, additionally a third byte for a baud rate prescaler extension of four bits (BREP) is provided. The sum of Prop_Seg and Phase_Seg1 (as TSEG1) is combined with Phase_Seg2 (as TSEG2) in one byte, SJW and BRP (plus BRPE in third byte) are combined in the other byte (see Figure 22-17).

Figure 22-17. Structure of the CAN Core's CAN Protocol Controller

In this bit timing register, the components TSEG1, TSEG2, SJW and BRP have to be programmed to a numerical value that is one less than its functional value; so instead of values in the range of [1…n], values in the range of [0…–1] are programmed. That way, e.g., SJW (functional range of [1…4]) is represented by only two bits.

Therefore, the length of the bit time is (programmed values) [TSEG1 + TSEG2 + 3] t_q or (functional values) [Sync_Seg + Prop_Seg + Phase_Seg1 + Phase_Seg2] t_q.

The data in the bit timing register (BTR) is the configuration input of the CAN protocol controller. The baud rate prescaler (configured by BRPE/BRP) defines the length of the time quantum (the basic time unit of the bit time); the bit timing logic (configured by TSEG1, TSEG2, and SJW) defines the number of time quanta in the bit time.

The processing of the bit time, the calculation of the position of the sample point, and occasional synchronizations are controlled by the bit timing state machine, which is evaluated once each time quantum. The rest of the CAN protocol controller, the bit stream processor (BSP) state machine, is evaluated once each bit time, at the sample point.

The shift register serializes the messages to be sent and parallelizes received messages. Its loading and shifting is controlled by the BSP. The BSP translates messages into frames and vice versa. It generates and discards the enclosing fixed format bits, inserts and extracts stuff bits, calculates and checks the CRC code, performs the error management, and decides which type of synchronization is to be used. It is evaluated at the sample point and processes the sampled bus input bit. The time after the sample point that is needed to calculate the next bit to be sent (e.g., data bit, CRC bit, stuff bit, error flag, or idle) is called the information processing time (IPT), which is 0 tq for the DCAN.

Copyright © 2011, Texas Instruments Incorporated

Generally, the IPT is CAN controller-specific, but may not be longer than 2 tq. The IPC length is the lower limit of the programmed length of Phase_Seg2. In case of a synchronization, Phase_Seg2 may be shortened to a value less than IPT, which does not affect bus timing.

22.3.9.2.1 Calculation of the Bit Timing Parameters

Usually, the calculation of the bit timing configuration starts with a desired bit rate or bit time. The resulting bit time (1 / Bit rate) must be an integer multiple of the CAN clock period.

NOTE: 8 MHz is the minimum CAN clock frequency required to operate the DCAN at a bit rate of 1 MBit/s.

The bit time may consist of 8 to 25 time quanta. The length of the time quantum t_q is defined by the baud rate prescaler with t_q = (Baud Rate Prescaler) / CAN_CLK. Several combinations may lead to the desired bit time, allowing iterations of the following steps.

First part of the bit time to be defined is the Prop_Seg. Its length depends on the delay times measured in the system. A maximum bus length as well as a maximum node delay has to be defined for expandible CAN bus systems. The resulting time for Prop_Seg is converted into time quanta (rounded up to the nearest integer multiple of t_q).

The Sync_Seg is 1 t_q long (fixed), leaving (bit time – Prop_Seg – 1) t_q for the two Phase Buffer Segments. If the number of remaining t_q is even, the Phase Buffer Segments have the same length, Phase_Seg2 = Phase_Seg1, else Phase_Seg2 = Phase_Seg1 + 1.

The minimum nominal length of Phase_Seg2 has to be regarded as well. Phase_Seg2 may not be shorter than any CAN controller's Information Processing Time in the network, which is device dependent and can be in the range of [0…2] t_q.

The length of the synchronization jump width is set to its maximum value, which is the minimum of four (4) and Phase_Seg1.

The oscillator tolerance range necessary for the resulting configuration is calculated by the formulas given in Section 22.3.9.2.3.

If more than one configurations are possible to reach a certain Bit rate, it is recommended to choose the configuration which allows the highest oscillator tolerance range.

CAN nodes with different clocks require different configurations to come to the same bit rate. The calculation of the propagation time in the CAN network, based on the nodes with the longest delay times, is done once for the whole network.

The CAN system's oscillator tolerance range is limited by the node with the lowest tolerance range.

The calculation may show that bus length or bit rate have to be decreased or that the oscillator frequencies' stability has to be increased in order to find a protocol compliant configuration of the CAN bit timing.

The resulting configuration is written into the bit timing register:

Tseg2 = Phase_Seg2-1

Tseg1 = Phase_Seg1+ Prop_Seg-1

SJW = SynchronizationJumpWidth-1

BRP = Prescaler-1

22.3.9.2.2 Example for Bit Timing at High Baud Rate

In this example, the frequency of CAN_CLK is 10 MHz, BRP is 0, the bit rate is 1 MBit/s.

t_{TSeg2}	3 µs	=	Information Processing Time + 3 • t_q
$t_{Sync\text{-}Seg}$	1 µs	=	1 • t_q
Bit time	9 µs	=	$t_{Sync\text{-}Seg}$ + t_{TSeg1} + t_{TSeg2}
Tolerance for CAN_CLK		=	$\frac{(\min(TSeg1, TSeg2))}{2x(13x(bit_time - TSeg2))}$
		=	$\frac{0.1\,\mu s}{2x(13x(1\,\mu s - 0.1\,\mu s))}$

In this example, the concatenated bit time parameters are $(3\text{-}1)_3$&$(5\text{-}1)_4$&$(4\text{-}1)_2$&$(2\text{-}1)_6$, so the bit timing register is programmed to = 0x000024C1.

22.3.10 Message Interface Register Sets

The interface register sets control the CPU read and write accesses to the message RAM. There are two interface registers sets for read/write access, IF1 and IF2 and one interface register set for read access only, IF3.

Due to the structure of the message RAM, it is not possible to change single bits or bytes of a message object. Instead, always a complete message object in the message RAM is accessed. Therefore the data transfer from the IF1/IF2 registers to the message RAM requires the message handler to perform a read-modify-write cycle: First those parts of the message object that are not to be changed are read from the message RAM into the interface register set, and after the update the whole content of the interface register set is written into the message object.

After the partial write of a message object, those parts of the interface register set that are not selected in the command register, will be set to the actual contents of the selected message object.

After the partial read of a message object, those parts of the interface register set that are not selected in the command register, will be left unchanged.

By buffering the data to be transferred, the interface register sets avoid conflicts between concurrent CPU accesses to the message RAM and CAN message reception and transmission. A complete message object (see Section 22.3.11.1) or parts of the message object may be transferred between the message RAM and the IF1/IF2 register set (see Section 22.5.19) in one single transfer. This transfer, performed in parallel on all selected parts of the message object, guarantees the data consistency of the CAN message.

22.3.10.1 Message Interface Register Sets 1 and 2

The IF1 and IF2 register sets control the data transfer to and from the message object. The command register addresses the desired message object in the message RAM and specifies whether a complete message object or only parts should be transferred. The data transfer is initiated by writing the message number to the bits [7:0] of the command register.

When the CPU initiates a data transfer between the IF1/IF2 registers and message RAM, the message handler sets the busy bit in the respective command register to ‘1’. After the transfer has completed, the busy bit is set back to ‘0’ (see Figure 22-18).

Figure 22-18. Data Transfer Between IF1/IF2 Registers and Message RAM

22.3.10.2 IF3 Register Set

The IF3 register set can automatically be updated with received message objects without the need to initiate the transfer from message RAM by CPU. The intention of this feature of IF3 is to provide an interface for the DMA to read packets efficiently. The automatic update functionality can be programmed for each message object (Section 22.5.28).

All valid message objects in message RAM which are configured for automatic update, will be checked for active NewDat flags. If such a message object is found, it will be transferred to the IF3 register (if no previous DMA transfers are ongoing), controlled by IF3 Observation register. If more than one NewDat flag is active, the message object with the lowest number has the highest priority for automatic IF3 update.

The NewDat bit in the message object will be reset by a transfer to IF3.

If DCAN internal IF3 update is complete, a DMA request is generated. The DMA request stays active until first read access to one of the IF3 registers. The DMA functionality has to be enabled by setting bit DE3 in CAN control register. Please refer to the device datasheet to find out if this DMA source is available.

NOTE: The IF3 register set can not be used for transferring data into message objects.

22.3.11 Message RAM

The DCAN message RAM contains message objects and parity bits for the message objects. There are up to 64 message objects in the message RAM.

During normal operation, accesses to the message RAM are performed via the interface register sets, and the CPU cannot directly access the message RAM.

The interface register sets IF1 and IF2 provide indirect read/write access from the CPU to the message RAM. The IF1 and IF2 register sets can buffer control and user data to be transferred to and from the message objects.

The third interface register set IF3 can be configured to automatically receive control and user data from the message RAM when a message object has been updated after reception of a CAN message. The CPU does not need to initiate the transfer from message RAM to IF3 register set.

The message handler avoids potential conflicts between concurrent accesses to message RAM and CAN frame reception/transmission.

There are two modes where the message RAM can be directly accessed by the CPU:

- Debug/Suspend mode (see Section 22.3.11.3)
- RAM Direct Access (RDA) mode (see Section 22.3.11.4)

For the message RAM base address, see the device-specific data sheet.

22.3.11.1 Structure of Message Objects

Table 22-8 shows the structure of a message object.

The grayed fields are those parts of the message object which are represented in dedicated registers. For example, the transmit request flags of all message objects are represented in centralized transmit request registers.

Table 22-8. Structure of a Message Object

Message Object												
UMask	**Msk[28:0]**	**MXtd**	**MDir**	**EoB**	**unused**	**NewDat**	**MsgLst**	**RxIE**	**TxIE**	**IntPnd**	**RmtEn**	**TxRqst**
MsgVal	ID[28:0]	Xtd	Dir	DLC[3:0]	Data 0	Data 1	Data 2	Data 3	Data 4	Data 5	Data 6	Data 7

Table 22-9. Field Descriptions

Name	Value	Description
MsgVal		Message valid
	0	The message object is ignored by the message handler.
	1	The message object is to be used by the message handler.
		Note: This bit may be kept at level ‘1’ even when the identifier bits ID[28:0], the control bits Xtd, Dir, or the data length code are changed. It should be reset if the Messages Object is no longer required.
UMask		Use acceptance mask
	0	Mask bits (Msk[28:0], MXtd and MDir) are ignored and not used for acceptance filtering.
	1	Mask bits are used for acceptance filtering.
		Note: If the UMask bit is set to one, the message object’s mask bits have to be programmed during initialization of the message object before MsgVal is set to one.
ID[28:0]		Message identifier
	ID[28:0]	29-bit (“extended”) identifier bits
	ID[28:18]	11-bit (“standard”) identifier bits
Msk[28:0]		Identifier mask
	0	The corresponding bit in the message identifier is not used for acceptance filtering (don’t care).
	1	The corresponding bit in the message identifier is used for acceptance filtering.
Xtd		Mask extended identifier
	0	The extended identifier bit (IDE) has no effect on the acceptance filtering.
	1	The extended identifier bit (IDE) is used for acceptance filtering.
		Note: When 11-bit (“standard”) Identifiers are used for a message object, the identifiers of received data frames are written into bits ID[28:18]. For acceptance filtering, only these bits together with mask bits Msk[28:18] are considered.
Dir		Message direction
	0	Direction = receive: On TxRqst, a remote frame with the identifier of this message object is transmitted. On reception of a data frame with matching identifier, the message is stored in this message object.
	1	Direction = transmit: On TxRqst, a data frame is transmitted. On reception of a remote frame with matching identifier, the TxRqst bit of this message object is set (if RmtEn = one).
MDir		Mask message direction
	0	The message direction bit (Dir) has no effect on the acceptance filtering.
	1	The message direction bit (Dir) is used for acceptance filtering.
EOB		End of block
	0	The message object is part of a FIFO Buffer block and is not the last message object of this FIFO Buffer block.
	1	The message object is a single message object or the last message object in a FIFO Buffer Block.
		Note: This bit is used to concatenate multiple message objects to build a FIFO Buffer. For single message objects (not belonging to a FIFO Buffer), this bit must always be set to one.

Table 22-9. Field Descriptions (continued)

Name	Value	Description
NewDat		New data
	0	No new data has been written into the data bytes of this message object by the message handler since the last time when this flag was cleared by the CPU.
	1	The message handler or the CPU has written new data into the data bytes of this message object.
MsgLst		Message lost (only valid for message objects with direction = receive)
	0	No message was lost since the last time when this bit was reset by the CPU.
	1	The message handler stored a new message into this message object when NewDat was still set, so the previous message has been overwritten.
RxIE		Receive interrupt enable
	0	IntPnd will not be triggered after the successful reception of a frame.
	1	IntPnd will be triggered after the successful reception of a frame.
TxIE		Transmit interrupt enable
	0	IntPnd will not be triggered after the successful transmission of a frame.
	1	IntPnd will be triggered after the successful transmission of a frame.
IntPnd		Interrupt pending
	0	This message object is not the source of an interrupt.
	1	This message object is the source of an interrupt. The interrupt Identifier in the interrupt register will point to this message object if there is no other interrupt source with higher priority.
RmtEn		Remote enable
	0	At the reception of a remote frame, TxRqst is not changed.
	1	At the reception of a remote frame, TxRqst is set.
TxRqst		Transmit request
	0	This message object is not waiting for a transmission.
	1	The transmission of this message object is requested and is not yet done.
DLC[3:0]		Data length code
	0	Data frame has 0-8 data bits.
	1	Data frame has 8 data bytes.
		Note: The data length code of a message object must be defined to the same value as in the corresponding objects with the same identifier at other nodes. When the message handler stores a data frame, it will write the DLC to the value given by the received message.
Data 0		1st data byte of a CAN data frame
Data 1		2nd data byte of a CAN data frame
Data 2		3rd data byte of a CAN data frame
Data 3		4th data byte of a CAN data frame
Data 4		5th data byte of a CAN data frame
Data 5		6th data byte of a CAN data frame
Data 6		7th data byte of a CAN data frame
Data 7		8th data byte of a CAN data frame
		Note: Byte Data 0 is the first data byte shifted into the shift register of the CAN core during a reception, byte Data 7 is the last. When the message handler stores a data frame, it will write all the eight data bytes into a message object. If the data length code is less than 8, the remaining bytes of the message object may be overwritten by undefined values.

22.3.11.2 Addressing Message Objects in RAM

The starting location of a particular message object in RAM is:
Message RAM base address + (message object number) * 0x20

This means that message object 1 starts at offset 0x0020; message object 2 starts at offset 0x0040, etc.

'0' is not a valid message object number.

The base address for DCAN0 RAM is 0x481C_D000 and DCAN1 RAM is 0x481D_1000.

Message object number 1 has the highest priority.

Table 22-10. Message RAM addressing in Debug/Suspend and RDA Mode

22.3.11.3 Message RAM Representation in Debug/Suspend Mode

In debug/suspend mode, the message RAM will be memory mapped. This allows the external debug unit to access the message RAM.

NOTE: During debug/suspend mode, the message RAM cannot be accessed via the IFx register sets.

Table 22-11. Message RAM Representation in Debug/Suspend Mode

Bit #	31/15	30/14	29/13	29/12	27/11	26/10	25/9	24/8	23/7	22/6	21/5	20/4	19/3	18/2	17/1	16/0

	Rsvd	MsgLst	Rsvd	UMask	TxIE	RxTE	RmtEn	Rsvd	EOB	Reserved			DLC[3:0]			
MsgAddr + 0x10	Data 3								Data 2							
	Data 1								Data 0							
MsgAddr + 0x14	Data 7								Data 6							
	Data 5								Data 4							

22.3.11.4 Message RAM Representation in Direct Access Mode

When the RDA bit in the test register is set while the DCAN module is in test mode (test bit in the CAN control register is set), the CPU has direct access to the message RAM. Due to the 32-bit bus structure, the RAM is split into word lines to support this feature. The CPU has access to one word line at a time only.

In RAM direct access mode, the RAM is represented by a continuous memory space within the address frame of the DCAN module, starting at the message RAM base address.

Note: During direct access mode, the message RAM cannot be accessed via the IFx register sets.

Any read or write to the RAM addresses for RamDirectAccess during normal operation mode (TestMode bit or RDA bit not set) will be ignored.

Table 22-12. Message RAM Representation in RAM Direct Access Mode

Bit #	31/15	30/14	29/13	29/12	27/11	26/10	25/9	24/8	23/7	22/6	21/5	20/4	19/3	18/2	17/1	16/0

NOTE: Writes to unused bits has no effect.

22.3.12 GIO Support

The CAN_RX and CAN_TX pins of the DCAN module can be used as general purpose IO pins, if CAN functionality is not needed. This function is controlled by the CAN TX IO control register (DCAN TIOC) (see Section 22.5.29) and the CAN RX IO control register (DCAN RIOC) (see Section 22.5.30).

22.4 Use Cases

22.5 DCAN Control Registers

The base address for the:

- DCAN0 registers are 0x481C_C000.
- DCAN1 registers are 0x481D_0000.

After hardware reset, the registers of the DCAN hold the values shown in the register descriptions.

Additionally, the Bus-Off state is reset and the CAN_TX pin is set to recessive (HIGH). The Init bit in the CAN control register is set to enable the software initialization. The DCAN will not influence the CAN bus until the CPU resets Init to '0'.

Table 22-14. CAN Control Register (DCAN CTL) Field Descriptions

Bit	Field	Value	Description
31-26	Reserved	0	These bits are always read as 0. Writes have no effect.
26	WUBA		Automatic wake up on bus activity when in local power-down mode
		0	No detection of a dominant CAN bus level while in local power-down mode.
		1	Detection of a dominant CAN bus level while in local power-down mode is enabled. On occurrence of a dominant CAN bus level, the wake up sequence is started (Additional information can be found in *Local Power-Down Mode*).
			Note: The CAN message, which initiates the bus activity, cannot be received. This means that the first message received in power down and automatic wake-up mode, will be lost.
24	PDR		Request for local low power-down mode
		0	No application request for local low power-down mode. If the application has cleared this bit while DCAN in local power-down mode, also the Init bit has to be cleared.
		1	Local power-down mode has been requested by application. The DCAN will acknowledge the local power-down mode by setting bit PDA in the error and status register. The local clocks will be turned off by DCAN internal logic (Additional information can be found in *Local Power-Down Mode*).
23-21	Reserved	0	These bits are always read as 0. Writes have no effect.
20	DE3		Enable DMA request line for IF3
		0	Disabled
		1	Enabled
			Note: A pending DMA request for IF3 remains active until first access to one of the IF3 registers.
19	DE2		Enable DMA request line for IF2
		0	Disabled
		1	Enabled
			Note: A pending DMA request for IF2 remains active until first access to one of the IF2 registers.
18	DE1		Enable DMA request line for IF1
		0	Disabled
		1	Enabled
			Note: A pending DMA request for IF1 remains active until first access to one of the IF1 registers.

Table 22-14. CAN Control Register (DCAN CTL) Field Descriptions (continued)

Bit	Field	Value	Description
17	IE1		Interrupt line 1 enable
		0	Disabled - Module interrupt DCAN1INT is always low.
		1	Enabled - interrupts will assert line DCAN1INT to one; line remains active until pending interrupts are processed.
16	InitDbg		Internal init state while debug access
		0	Not in debug mode, or debug mode requested but not entered.
		1	Debug mode requested and internally entered; the DCAN is ready for debug accesses.
15	SWR		SW reset enable
		0	Normal Operation
		1	Module is forced to reset state. This bit will automatically get cleared after execution of SW reset after one OCP clock cycle. Note: To execute software reset, the following procedure is necessary: 1. Set Init bit to shut down CAN communication. 2. Set SWR bit additionally to Init bit.
14	Reserved	0	This bit is always read as 0. Writes have no effect.
13-10	PMD		Parity on/off
		0x5	Parity function disabled
		Others	Parity function enabled
9	ABO		Auto-Bus-On enable
		0	The Auto-Bus-On feature is disabled
		1	The Auto-Bus-On feature is enabled
8	IDS		Interruption debug support enable
		0	When Debug/Suspend mode is requested, DCAN will wait for a started transmission or reception to be completed before entering Debug/Suspend mode
		1	When Debug/Suspend mode is requested, DCAN will interrupt any transmission or reception, and enter Debug/Suspend mode immediately.
7	Test		Test mode enable
		0	Normal Operation
		1	Test Mode
6	CCE		Configuration change enable
		0	The CPU has no write access to the configuration registers.
		1	The CPU has write access to the configuration registers (when Init bit is set).
5	DAR		Disable automatic retransmission
		0	Automatic retransmission of not successful messages enabled.
		1	Automatic retransmission disabled.
4	Reserved	0	This bit is always read as 0. Writes have no effect.
3	EIE		Error interrupt enable
		0	Disabled - PER, BOff and EWarn bits can not generate an interrupt.
		1	Enabled - PER, BOff and EWarn bits can generate an interrupt at DCAN0INT line and affect the interrupt register.
2	SIE		Status change interrupt enable
		0	Disabled - WakeUpPnd, RxOk, TxOk and LEC bits can not generate an interrupt.
		1	Enabled - WakeUpPnd, RxOk, TxOk and LEC can generate an interrupt at DCAN0INT line and affect the interrupt register.
1	IE0		Interrupt line 0 enable
		0	Disabled - Module interrupt DCAN0INT is always low.
		1	Enabled - interrupts will assert line DCAN0INT to one; line remains active until pending interrupts are processed.

Table 22-14. CAN Control Register (DCAN CTL) Field Descriptions (continued)

Bit	Field	Value	Description
0	Init		Initialization
		0	Normal operation
		1	Initialization mode is entered

NOTE: The Bus-Off recovery sequence (refer to CAN specification) cannot be shortened by setting or resetting Init bit. If the module goes Bus-Off, it will automatically set the Init bit and stop all bus activities.

When the Init bit is cleared by the application again, the module will then wait for 129 occurrences of Bus Idle (129 * 11 consecutive recessive bits) before resuming normal operation. At the end of the bus-off recovery sequence, the error counters will be reset.

After the Init bit is reset, each time when a sequence of 11 recessive bits is monitored, a Bit0 error code is written to the error and status register, enabling the CPU to check whether the CAN bus is stuck at dominant or continuously disturbed, and to monitor the proceeding of the bus-off recovery sequence.

22.5.2 Error and Status Register (DCAN ES) and DCAN Parity Error EOI Register (PARITYERR_EOI)

The error and status register (DCAN ES) is shown in Figure 22-20 and described in Table 22-15. The DCAN Parity Error EOI register is shown in Figure 22-21 and described in Table 22-16.

Figure 22-20. Error and Status Register (DCAN ES)

Table 22-15. Error and Status Register (DCAN ES) Field Descriptions (continued)

Bit	Field	Value	Description
9	WakeUp Pnd		Wake up pending. This bit can be used by the CPU to identify the DCAN as the source to wake up the system.
		0	No Wake Up is requested by DCAN.
		1	DCAN has initiated a wake up of the system due to dominant CAN bus while module power down.
			This bit will be reset if error and status register is read.
8	PER		Parity error detected
		0	No parity error has been detected since last read access.
		1	The parity check mechanism has detected a parity error in the Message RAM.
			This bit will be reset if error and status register is read.
7	BOff		Bus-Off state
		0	The CAN module is not bus-off state.
		1	The CAN module is in bus-off state.
6	EWarn		Warning state
		0	Both error counters are below the error warning limit of 96.
		1	At least one of the error counters has reached the error warning limit of 96.
5	EPass		Error passive state
		0	On CAN Bus error, the DCAN could send active error frames.
		1	The CAN core is in the error passive state as defined in the CAN Specification.
4	RxOk		Received a message successfully
		0	No message has been successfully received since the last time when this bit was read by the CPU. This bit is never reset by DCAN internal events.
		1	A message has been successfully received since the last time when this bit was reset by a read access of the CPU (independent of the result of acceptance filtering).
			This bit will be reset if error and status register is read.
3	TxOk		Transmitted a message successfully
		0	No message has been successfully transmitted since the last time when this bit was read by the CPU. This bit is never reset by DCAN internal events.
		1	A message has been successfully transmitted (error free and acknowledged by at least one other node) since the last time when this bit was reset by a read access of the CPU.
			This bit will be reset if error and status register is read.
2-0	LEC		Last error code. The LEC field indicates the type of the last error on the CAN bus. This field will be cleared to '0' when a message has been transferred (reception or transmission) without error.
		0	No error
		1	Stuff error: More than five equal bits in a row have been detected in a part of a received message where this is not allowed.
		2	Form error: A fixed format part of a received frame has the wrong format.
		3	Ack error: The message this CAN core transmitted was not acknowledged by another node.
		4	Bit1 error: During the transmission of a message (with the exception of the arbitration field), the device wanted to send a recessive level (bit of logical value '1'), but the monitored bus value was dominant.
		5	Bit0 error: During the transmission of a message (or acknowledge bit, or active error flag, or overload flag), the device wanted to send a dominant level (logical value '0'), but the monitored bus level was recessive. During Bus-Off recovery, this status is set each time a sequence of 11 recessive bits has been monitored. This enables the CPU to monitor the proceeding of the Bus-Off recovery sequence (indicating the bus is not stuck at dominant or continuously disturbed).
		6	CRC error: In a received message, the CRC check sum was incorrect. (CRC received for an incoming message does not match the calculated CRC for the received data).
		7	No CAN bus event was detected since the last time the CPU read the error and status register. Any read access to the error and status register re-initializes the LEC to value '7.'

Table 22-16. Parity Error End of Interrupt Register (PARITYERR_EOI) Field Descriptions

Bit	Field	Value	Description
31-9	Reserved	0	These bits are always read as 0. Writes have no effect.
8	PARITYERR_ EOI		End of interrupt indication for parity error
		0	Has no effect writing
		1	Indicated end of interrupt for parity error
7-0	Reserved		These bits are always read as 0. Writes have no effect.

Interrupts are generated by bits PER, BOff and EWarn (if EIE bit in CAN control register is set) and by bits WakeUpPnd, RxOk, TxOk, and LEC (if SIE bit in CAN control register is set).

A change of bit EPass will not generate an interrupt.

PARITYERR_EOI is used to signal an end of interrupt of the parity error interrupt (dcan_parity) to the IP. PARITYERR_EOI register is a *Write only* register.

A read from this offset address will result in a read from the DCAN ES register, where as a write will result in a write to the PARITYERR_EOI register.

NOTE: Reading the error and status register clears the WakeUpPnd, PER, RxOk and TxOk bits and set the LEC to value '7.' Additionally, the status interrupt value (0x8000) in the interrupt register will be replaced by the next lower priority interrupt value. The EOI for all other interrupts (DCANINT0 and DCANINT1) are automatically handled by hardware.

NOTE: For debug support, the auto clear functionality of error and status register (clear of status flags by read) is disabled when in debug/suspend mode.

22.5.3 Error Counter Register (DCAN ERRC)

The error counter register (DCAN ERRC) is shown in Figure 22-22 and described in Table 22-17.

Figure 22-22. Error Counter Register (DCAN ERRC)

31–16	15	14–8	7–0
Reserved	RP	REC[6:0]	TEC[7:0]
R-0	R-0	R-0	R-0

LEGEND: R = Read only; -*n* = value after reset

Table 22-17. Error Counter Register (DCAN ERRC) Field Descriptions

Bit	Field	Value	Description
31-16	Reserved	0	These bits are always read as 0. Writes have no effect.
15	RP		Receive error passive
		0	The receive error counter is below the error passive level.
		1	The receive error counter has reached the error passive level as defined in the CAN specification.
14-8	REC[6:0]		Receive error counter. Actual state of the receive error counter (values from 0 to 255).
7-0	TEC[7:0]		Transmit error counter. Actual state of the transmit error counter (values from 0 to 255).

22.5.4 Bit Timing Register (DCAN BTR)

The bit timing register (DCAN BTR) is shown in Figure 22-23 and described in Table 22-18.

Figure 22-23. Bit Timing Register (DCAN BTR)

31–20	19–16
Reserved	BRPE
R-0	R-0

15	14–12	11–8	7–6	5–0
Reserved	TSeg2	TSeg1	SJW	BRP
R-0	R/WP-0x2	R/WP-0x3	R/WP-0	R/WP-0x1

LEGEND: R = Read only; WP = Write protected by CCE bit; -*n* = value after reset

Table 22-18. Bit Timing Register (DCAN BTR) Field Descriptions

Bit	Field	Value	Description
31-20	Reserved	0	These bits are always read as 0. Writes have no effect.
19-16	BRPE	0x00-0x0F	Baud rate prescaler extension. Valid programmed values are 0 to 15. By programming BRPE the baud rate prescaler can be extended to values up to 1024.
15	Reserved	0	These bits are always read as 0. Writes have no effect.
14-12	TSeg2	0x0-0x7	Time segment after the sample point Valid programmed values are 0 to 7. The actual TSeg2 value which is interpreted for the bit timing will be the programmed TSeg2 value + 1.
11-8	TSeg1	0x01-0x0F	Time segment before the sample point Valid programmed values are 1 to15. The actual TSeg1 value interpreted for the bit timing will be the programmed TSeg1 value + 1.
7-6	SJW	0x0-0x3	Synchronization Jump Width Valid programmed values are 0 to 3. The actual SJW value interpreted for the synchronization will be the programmed SJW value + 1.
5-0	BRP	0x00-0x3F	Baud rate prescaler Value by which the CAN_CLK frequency is divided for generating the bit time quanta. The bit time is built up from a multiple of this quanta. Valid programmed values are 0 to 63. The actual BRP value interpreted for the bit timing will be the programmed BRP value + 1.

NOTE: This register is only writable if CCE and Init bits in the CAN control register are set.

NOTE: The CAN bit time may be programmed in the range of 8 to 25 time quanta.

NOTE: The CAN time quantum may be programmed in the range of 1 to1024 CAN_CLK periods.

With a CAN_CLK of 8 MHz and BRPE = 0x00, the reset value of 0x00002301 configures the DCAN for a bit rate of 500kBit/s.

22.5.5 Interrupt Register (DCAN INT)

The interrupt register (DCAN INT) is shown in Figure 22-24 and described in Table 22-19.

Figure 22-24. Interrupt Register (DCAN INT)

31–24	23–16
Reserved	Int1ID[7:0]
R-0	R-0

15–0
Int0ID[15:0]
R-0

LEGEND: R = Read only; -*n* = value after reset

Table 22-19. Interrupt Register (DCAN INT) Field Descriptions

Bit	Field	Value	Description
31-24	Reserved	0	These bits are always read as 0. Writes have no effect.
23-16	Int1ID[23:16]		Interrupt 1 Identifier (indicates the message object with the highest pending interrupt)
		0x00	No interrupt is pending
		0x01-0x80	Number of message object which caused the interrupt.
		0x81-0xFF	Unused
			If several interrupts are pending, the CAN interrupt register will point to the pending interrupt with the highest priority. The DCAN1INT interrupt line remains active until Int1ID reaches value 0 (the cause of the interrupt is reset) or until IE1 is cleared.
			A message interrupt is cleared by clearing the message object's IntPnd bit.
			Among the message interrupts, the message object's interrupt priority decreases with increasing message number.
15-0	Int0ID[15:0]		Interrupt Identifier (the number here indicates the source of the interrupt)
		0x0000	No interrupt is pending
		0x0001-0x0080	Number of message object which caused the interrupt.
		0x0081-0x7FFF	Unused
		0x8000	Error and status register value is not 0x07.
		0x8001-0xFFFF	Unused
			If several interrupts are pending, the CAN interrupt register will point to the pending interrupt with the highest priority. The DCAN0INT interrupt line remains active until Int0ID reaches value 0 (the cause of the interrupt is reset) or until IE0 is cleared.
			The Status interrupt has the highest priority. Among the message interrupts, the message object's interrupt priority decreases with increasing message number.

22.5.6 Test Register (DCAN TEST)

The test register (DCAN TEST) is shown in Figure 22-25 and described in Table 22-20.

Figure 22-25. Test Register (DCAN TEST)

31											16
Reserved											
R-0											

15	10	9	8	7	6	5	4	3	2	1	0
Reserved		RDA	EXL	Rx	Tx[1:0]		LBack	Silent	Reserved		
R-0		R/WP-0	R/WP-0	R-U	R/WP-0		R/WP-0	R/WP-0	R-0		

LEGEND: R = Read only; WP = Write protected by test bit; -*n* = value after reset; U = Undefined

Table 22-20. Test Register (DCAN TEST) Field Descriptions

Bit	Field	Value	Description
31-10	Reserved	0	These bits are always read as 0. Writes have no effect.
9	RDA		RAM direct access enable
		0	Normal pperation
		1	Direct access to the RAM is enabled while in test mode
8	EXL		External loopback mode
		0	Disabled
		1	Enabled
7	Rx		Receive pin. Monitors the actual value of the CAN_RX pin
		0	The CAN bus is dominant
		1	The CAN bus is recessive
6-5	Tx[1:0]		Control of CAN_TX pin
		00	Normal operation, CAN_TX is controlled by the CAN core.
		01	Sample point can be monitored at CAN_TX pin.
		10	CAN_TX pin drives a dominant value.
		11	CAN_TX pin drives a recessive value.
4	LBack		Loopback mode
		0	Disabled
		1	Enabled
3	Silent		Silent mode
		0	Disabled
		1	Enabled
2-0	Reserved	0	These bits are always read as 0. Writes have no effect.

For all test modes, the test bit in CAN control register needs to be set to one. If test bit is set, the RDA, EXL, Tx1, Tx0, LBack and Silent bits are writable. Bit Rx monitors the state of pin CAN_RX and therefore is only readable. All test register functions are disabled when test bit is cleared.

NOTE: The test register is only writable if test bit in CAN control register is set.

NOTE: Setting Tx[1:0] other than '00' will disturb message transfer.

NOTE: When the internal loop-back mode is active (bit LBack is set), bit EXL will be ignored.

22.5.7 Parity Error Code Register (DCAN PERR)

The parity error code register (DCAN PERR) is shown in Figure 22-26 and described in Table 22-21.

Figure 22-26. Parity Error Code Register (DCAN PERR)

31–16	15–11	10–8	7–0
Reserved	Reserved	Word Number	Message Number
R-0	R-0	R-U	R-U

LEGEND: R = Read only; -*n* = value after reset; U = Undefined

Table 22-21. Parity Error Code Register (DCAN PERR) Field Descriptions

Bit	Field	Value	Description
31-11	Reserved	0	These bits are always read as 0. Writes have no effect.
10-8	Word Number	0x01-0x05	Word number where parity error has been detected RDA word number (1 to 5) of the message object (according to the message RAM representation in RDA mode).
7-0	Message Number	0x01-0x80	Message object number where parity error has been detected

If a parity error is detected, the PER flag will be set in the error and status register. This bit is not reset by the parity check mechanism; it must be reset by reading the error and status register.

In addition to the PER flag, the parity error code register will indicate the memory area where the parity error has been detected (message number and word number).

If more than one word with a parity error was detected, the highest word number with a parity error will be displayed.

After a parity error has been detected, the register will hold the last error code until power is removed.

22.5.8 Auto-Bus-On Time Register (DCAN ABOTR)

The Auto-Bus-On time register (DCAN ABOTR) is shown in Figure 22-27 and described in Table 22-22.

Figure 22-27. Auto-Bus-On Time Register (DCAN ABOTR)

31 – 16	15 – 0
ABO Time[31:16]	ABO Time[15:0]
R/W-0	R/W-0

LEGEND: R = Read only; W = Write only; -*n* = value after reset

Table 22-22. Auto-Bus-On Time Register (DCAN ABOTR) Field Descriptions

Bit	Field	Value	Description
31-0	ABO Time		Number of OCP clock cycles before a Bus-Off recovery sequence is started by clearing the Init bit. This function has to be enabled by setting bit ABO in CAN control register. The Auto-Bus-On timer is realized by a 32-bit counter that starts to count down to zero when the module goes Bus-Off. The counter will be reloaded with the preload value of the ABO time register after this phase.

NOTE: On write access to the CAN control register while Auto-Bus-On timer is running, the Auto-Bus-On procedure will be aborted.

NOTE: During Debug/Suspend mode, running Auto-Bus-On timer will be paused.

22.5.15 Message Valid X Register (DCAN MSGVAL X)

With the message valid X register, the CPU can detect if one or more bits in the different message valid registers are set. Each bit of this register represents a group of eight message objects. If at least one of the MsgVal bits of these message objects are set, the corresponding bit in the message valid X register will be set.

The message valid X register (DCAN MSGVAL X) is shown in Figure 22-31.

Figure 22-31. Message Valid X Register (DCAN MSGVAL X)

22.5.16 Message Valid Registers (DCAN MSGVAL12 to DCAN MSGVAL78)

These registers hold the MsgVal bits of the implemented message objects. By reading out these bits, the CPU can check which message objects are valid. The MsgVal bit of a specific message object can be set/reset by the CPU via the IF1/IF2 interface register sets, or by the message handler after a reception or a successful transmission.

The message valid registers (DCAN MSGVAL12 to MSGVAL78) is shown in Table 22-29 and described in Table 22-30.

Table 22-29. Message Valid Registers (DCAN MSGVAL12 to DCAN MSGVAL78)

22.5.17 Interrupt Multiplexer Registers (DCAN INTMUX12 to DCAN INTMUX78)

The IntMux flag determine for each message object, which of the two interrupt lines (DCAN0INT or DCAN1INT) will be asserted when the IntPnd of this message object is set. Both interrupt lines can be globally enabled or disabled by setting or clearing IE0 and IE1 bits in CAN control register.

The IntPnd bit of a specific message object can be set or reset by the CPU via the IF1/IF2 interface register sets, or by message handler after reception or successful transmission of a frame. This will also affect the Int0ID resp Int1ID flags in the interrupt register.

The interrupt multiplexer registers are shown in Table 22-31 and described in Table 22-32.

Table 22-31. Interrupt Multiplexer Registers (DCAN INTMUX12 to DCAN INTMUX78)

Offset/Register	31/15	30/14	29/13	29/12	27/11	26/10	25/9	24/8	23/7	22/6	21/5	20/4	19/3	18/2	17/1	16/0

22.5.18 IF1/IF2 Command Registers (DCAN IF1CMD, DCAN IF2CMD)

The IF1/IF2 Command Register (DCAN IF1CMD, DCAN IF2CMD) configure and initiate the transfer between the IF1/IF2 register sets and the message RAM. It is configurable which portions of the message object should be transferred.

A transfer is started when the CPU writes the message number to bits [7:0] of the IF1/IF2 command register. With this write operation, the Busy bit is automatically set to '1' to indicate that a transfer is in progress.

After 4 to 14 OCP clock cycles, the transfer between the interface register and the message RAM will be completed and the Busy bit is cleared. The maximum number of cycles is needed when the message transfer concurs with a CAN message transmission, acceptance filtering, or message storage.

If the CPU writes to both IF1/IF2 command registers consecutively (request of a second transfer while first transfer is still in progress), the second transfer will start after the first one has been completed.

The IF1/IF2 command registers are shown in Figure 22-32 and Figure 22-33 and described in Table 22-33.

NOTE: While Busy bit is one, IF1/IF2 register sets are write protected.

NOTE: For debug support, the auto clear functionality of the IF1/IF2 command registers (clear of DMAactive flag by r/w) is disabled during Debug/Suspend mode.

NOTE: If an invalid Message Number is written to bits [7:0] of the IF1/IF2 command register, the message handler may access an implemented (valid) message object instead.

Table 22-33. IF1/IF2 Command Registers (DCAN IF1CMD, DCAN IF2CMD) Field Descriptions

Bit	Field	Value	Description
31-24	Reserved	0	These bits are always read as 0. Writes have no effect.
23	WR/RD		Write/Read
		0	Direction = Read: Transfer direction is from the message object addressed by Message Number (Bits [7:0]) to the IF1/IF2 register set.
		1	Direction = Write: Transfer direction is from the IF1/IF2 register set to the message object addressed by Message Number (Bits [7:0]).
22	Mask		Access mask bits
		0	Mask bits will not be changed
		1	Direction = Read: The mask bits (identifier mask + MDir + MXtd) will be transferred from the message object addressed by Message Number (Bits [7:0]) to the IF1/IF2 register set.
			Direction = Write: The mask bits (identifier mask + MDir + MXtd) will be transferred from the IF1/IF2 register set to the message object addressed by Message Number (Bits [7:0]).
21	Arb		Access arbitration bits
		0	Arbitration bits will not be changed
		1	Direction = Read: The Arbitration bits (Identifier + Dir + Xtd + MsgVal) will be transferred from the message object addressed by Message Number (Bits [7:0]) to the corresponding IF1/IF2 register set.
			Direction = Write: The Arbitration bits (Identifier + Dir + Xtd + MsgVal) will be transferred from the IF1/IF2 register set to the message object addressed by Message Number (Bits [7:0]).
20	Control		Access control bits
		0	Control bits will not be changed
		1	Direction = Read: The message control bits will be transferred from the message object addressed by message number (Bits [7:0]) to the IF1/IF2 registerset.
			Direction = Write: The message control bits will be transferred from the IF1/IF2 registerset to the message object addressed by message number (Bits [7:0]).
			If the TxRqst/NewDat bit in this register(Bit [18]) is set, the TxRqst/ NewDat bit in the IF1/IF2 message control register will be ignored.
19	ClrIntPnd		Clear interrupt pending bit
		0	IntPnd bit will not be changed
		1	Direction = Read: Clears IntPnd bit in the message object.
			Direction = Write: This bit is ignored. Copying of IntPnd flag from IF1/IF2 Registers to message RAM can only be controlled by the control flag (Bit [20]).
18	TxRqst/NewDat		Access transmission request bit
		0	Direction = Read: NewDat bit will not be changed. Direction = Write: TxRqst/NewDat bit will be handled according to the control bit.
		1	Direction = Read: Clears NewDat bit in the message object. Direction = Write: Sets TxRqst/NewDat in message object.
			Note: If a CAN transmission is requested by setting TxRqst/NewDat in this register, the TxRqst/NewDat bits in the message object will be set to one independent of the values in IF1/IF2 message control Register.
			Note: A read access to a message object can be combined with the reset of the control bits IntPnd and NewDat. The values of these bits transferred to the IF1/IF2 message control registeralways reflect the status before resetting them.
17	Data A		Access Data Bytes 0-3
		0	Data Bytes 0-3 will not be changed.
		1	Direction = Read: The data bytes 0-3 will be transferred from the message object addressed by the Message Number (Bits [7:0]) to the corresponding IF1/IF2 registerset.
			Direction = Write: The data bytes 0-3 will be transferred from the IF1/IF2 registerset to the message object addressed by the Message Number (Bits [7:0]).
			Note: The duration of the message transfer is independent of the number of bytes to be transferred.

Table 22-33. IF1/IF2 Command Registers (DCAN IF1CMD, DCAN IF2CMD) Field Descriptions (continued)

Bit	Field	Value	Description
16	Data B		Access Data Bytes 4-7
		0	Data Bytes 4-7 will not be changed.
		1	Direction = Read: The data bytes 4-7 will be transferred from the message object addressed by Message Number (Bits [7:0]) to the corresponding IF1/IF2 registerset. Direction = Write: The data bytes 4-7 will be transferred from the IF1/IF2 registerset to the message object addressed by message number (Bits [7:0]). Note: The duration of the message transfer is independent of the number of bytes to be transferred.
15	Busy		Busy flag
		0	No transfer between IF1/IF2 register set and message RAM is in progress.
		1	Transfer between IF1/IF2 register set and message RAM is in progress. This bit is set to one after the message number has been written to bits [7:0]. IF1/IF2 register set will be write protected. The bit is cleared after read/write action has been finished.
14	DMAactive		Activation of DMA feature for subsequent internal IF1/IF2 update
		0	DMA request line is independent of IF1/IF2 activities.
		1	DMA is requested after completed transfer between IF1/IF2 register set and message RAM. The DMA request remains active until the first read or write to one of the IF1/IF2 registers; an exception is a write to Message Number (Bits [7:0]) when DMAactive is one. Note: Due to the auto reset feature of the DMAactive bit, this bit has to be set for each subsequent DMA cycle separately.
13-8	Reserved	0	These bits are always read as 0. Writes have no effect.
7-0	Message Number		Number of message object in message RAM which is used for data transfer
		0x00	Invalid message number
		0x01-0x80	Valid message numbers
		0x81-0xFF	Invalid message numbers

22.5.19 IF1/IF2 Mask Registers (DCAN IF1MSK, DCAN IF2MSK)

The bits of the IF1/IF2 mask registers mirror the mask bits of a message object. The function of the relevant message objects bits is described in *Structure of Message Objects*.

The IF1/IF2 mask registers (DCAN IF1MSK, DCAN IF2MSK) are shown in Figure 22-34 and Figure 22-35 and described in Table 22-34.

NOTE: While Busy bit of IF1/IF2 command register is one, IF1/IF2 register set is write protected.

Figure 22-34. IF1 Mask Register (DCAN IF1MSK)

31	30	29	28 … 16

Table 22-34. IF1/IF2 Mask Registers (DCAN IF1MSK, DCAN IF2MSK) Field Descriptions

Bit	Field	Value	Description
31	MXtd		Mask Extended Identifier
		0	The extended identifier bit (IDE) has no effect on the acceptance filtering.
		1	The extended identifier bit (IDE) is used for acceptance filtering.
			When 11-bit ("standard") identifiers are used for a message object, the identifiers of received data frames are written into bits ID[28:18]. For acceptance filtering, only these bits together with mask bits Msk[28:18] are considered.
30	MDir		Mask Message Direction
		0	The message direction bit (Dir) has no effect on the acceptance filtering.
		1	The message direction bit (Dir) is used for acceptance filtering.
29	Reserved	0	These bits are always read as 0. Writes have no effect.
28-0	Msk[28:0]		Identifier Mask
		0	The corresponding bit in the identifier of the message object is not used for acceptance filtering (don't care).
		1	The corresponding bit in the identifier of the message object is used for acceptance filtering.

22.5.20 IF1/IF2 Arbitration Registers (DCAN IF1ARB, DCAN IF2ARB)

The bits of the IF1/IF2 arbitration registers mirror the arbitration bits of a message object. The function of the relevant message objects bits is described in *Structure of Message Objects*.

The IF1/IF2 arbitration registers (DCAN IF1ARB, DCAN IF2ARB) are shown in Figure 22-36 and Figure 22-37 and described in Table 22-35.

NOTE: While Busy bit of IF1/IF2 command register is one, IF1/IF2 register set is write protected.

Figure 22-36. IF1 Arbitration Register (DCAN IF1ARB)

R/WP-0

LEGEND: R = Read only; WP = Write protected (protected by busy bit); -*n* = value after reset

Table 22-35. IF1/IF2 Arbitration Registers (DCAN IF1ARB, DCAN IF2ARB) Field Descriptions

Bit	Field	Value	Description
31	MsgVal		Message valid
		0	The message object is ignored by the message handler.
		1	The message object is to be used by the message handler.
			The CPU should reset the MsgVal bit of all unused Messages Objects during the initialization before it resets bit Init in the CAN control register. This bit must also be reset before the identifier ID[28:0], the control bits Xtd, Dir or DLC[3:0] are modified, or if the messages object is no longer required.
30	Xtd		Extended identifier
		0	The 11-bit (“standard”) Identifier is used for this message object.
		1	The 29-bit (“extended”) Identifier is used for this message object.
29	Dir		Message direction
		0	Direction = receive: On TxRqst, a remote frame with the identifier of this message object is transmitted. On reception of a data frame with matching identifier, this message is stored in this message object.
		1	Direction = transmit: On TxRqst, the respective message object is transmitted as a data frame. On reception of a remote frame with matching identifier, the TxRqst bit of this message object is set (if RmtEn = 1).

Copyright © 2011, Texas Instruments Incorporated

Table 22-35. IF1/IF2 Arbitration Registers (DCAN IF1ARB, DCAN IF2ARB) Field Descriptions (continued)

Bit	Field	Value	Description
28-0	Msk[28:0]		Message identifier
		ID[28:0]	29-bit identifier (extended frame)
		ID[28:18]	11-bit identifier (standard frame)

The Arbitration bits ID[28:0], Xtd, and Dir are used to define the identifier and type of outgoing messages and (together with the mask bits Msk[28:0], MXtd, and MDir) for acceptance filtering of incoming messages.

A received message is stored into the valid message object with matching identifier and Direction = receive (data frame) or Direction = transmit (remote frame).

Extended frames can be stored only in message objects with Xtd = one, standard frames in message objects with Xtd = zero.

If a received message (data frame or remote frame) matches more than one valid message objects, it is stored into the one with the lowest message number.

R/WP-0	R/WP-0	R/WP-0	R/WP-0	R/WP-0	R/WP-0	R/WP-0	R/WP-0	R/WP-0	R/WP-0			R/WP-0			

LEGEND: R = Read only; WP = Protected Write (protected by Busy bit); -*n* = value after reset

Table 22-36. IF1/IF2 Message Control Registers (DCAN IF1MCTL, DCAN IF2MCTL) Field Descriptions

Bit	Field	Value	Description
31-16	Reserved	0	These bits are always read as 0. Writes have no effect.
15	NewDat		New data
		0	No new data has been written into the data portion of this message object by the message handler since the last time when this flag was cleared by the CPU.
		1	The message handler or the CPU has written new data into the data portion of this message object.
14	MsgLst		Message lost (only valid for message objects with direction = receive)
		0	No message lost since the last time when this bit was reset by the CPU.
		1	The message handler stored a new message into this object when NewDat was still set, so the previous message has been overwritten.
13	IntPnd		Interrupt pending
		0	This message object is not the source of an interrupt.
		1	This message object is the source of an interrupt. The Interrupt Identifier in the interrupt register will point to this message object if there is no other interrupt source with higher priority.
12	UMask		Use acceptance mask
		0	Mask ignored
		1	Use mask (Msk[28:0], MXtd, and MDir) for acceptance filtering
			If the UMask bit is set to one, the message object's mask bits have to be programmed during initialization of the message object before MsgVal is set to one.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Table 22-36. IF1/IF2 Message Control Registers (DCAN IF1MCTL, DCAN IF2MCTL) Field Descriptions (continued)

Bit	Field	Value	Description
11	TxIE		Transmit interrupt enable
		0	IntPnd will not be triggered after the successful transmission of a frame.
		1	IntPnd will be triggered after the successful transmission of a frame.
10	RxIE		Receive interrupt enable
		0	IntPnd will not be triggered after the successful reception of a frame.
		1	IntPnd will be triggered after the successful reception of a frame.
9	RmtEn		Remote enable
		0	At the reception of a remote frame, TxRqst is not changed.
		1	At the reception of a remote frame, TxRqst is set.
8	TxRqst		Transmit request
		0	This message object is not waiting for a transmission.
		1	The transmission of this message object is requested and is not yet done.
7	EoB		Data frame has 0-8 data bits.
		0	Data frame has 8 data bytes.
		1	Note: The data length code of a message object must be defined the same as in all the corresponding objects with the same identifier at other nodes. When the message handler stores a data frame, it will write the DLC to the value given by the received message.
			Note: This bit is used to concatenate multiple message objects to build a FIFO Buffer. For single message objects (not belonging to a FIFO Buffer), this bit must always be set to one.
6-4	Reserved	0	These bits are always read as 0. Writes have no effect.
3-0			Data length code
		0-8	Data frame has 0-8 data bits.
		9-15	Data frame has 8 data bytes.
			Note: The data length code of a message object must be defined the same as in all the corresponding objects with the same identifier at other nodes. When the message handler stores a data frame, it will write the DLC to the value given by the received message.

22.5.22 IF1/IF2 Data A and Data B Registers (DCAN IF1DATA/DATB, DCAN IF2DATA/DATB)

The data bytes of CAN messages are stored in the IF1/IF2 registers in the following order:

1. In a CAN data frame, Data 0 is the first, and Data 7 is the last byte to be transmitted or received.
2. In CAN's serial bit stream, the MSB of each byte will be transmitted first.

The IF1/IF2 data A and data B registers (DCAN IF1DATA/DATB, DCAN IF2DATA/DATB) registers are shown in Figure 22-40, Figure 22-41, Figure 22-42 and Figure 22-43.

22.5.23 IF3 Observation Register (DCAN IF3OBS)

The IF3 register set can automatically be updated with received message objects without the need to initiate the transfer from message RAM by CPU (Additional information can be found in *Structure of Message Objects*).

The observation flags (Bits [4:0]) in the IF3 observation register are used to determine, which data sections of the IF3 interface register set have to be read in order to complete a DMA read cycle. After all marked data sections are read, the DCAN is enabled to update the IF3 interface register set with new data.

Any access order of single bytes or half-words is supported. When using byte or half-word accesses, a data section is marked as completed, if all bytes are read.

NOTE: If IF3 Update Enable is used and no Observation flag is set, the corresponding message objects will be copied to IF3 without activating the DMA request line and without waiting for DMA read accesses.

A write access to this register aborts a pending DMA cycle by resetting the DMA line and enables updating of IF3 interface register set with new data. To avoid data inconsistency, the DMA controller should be disabled before reconfiguring IF3 observation register.

The status of the current read-cycle can be observed via status flags (Bits [12:8]).

If an interrupt line is available for IF3, an interrupt will be generated by IF3Upd flag. See the device-specific data sheet for the availability of this interrupt source.

With this interrupt, the observation status bits and the IF3Upd bit could be used by the application to realize the notification about new IF3 content in polling or interrupt mode.

The IF3 observation register (DCAN IF3OBS) is shown in Figure 22-44 and described in Table 22-37.

Figure 22-44. IF3 Observation Register (DCAN IF3OBS)

22.5.25 IF3 Arbitration Register (DCAN IF3ARB)

The IF3 arbitration register (DCAN IF3ARB) is shown in Figure 22-46 and described in Table 22-39.

Figure 22-46. IF3 Arbitration Register (DCAN IF3ARB)

31	30	29	28 … 16
MsgVal	Xtd	Dir	ID[28:16]
R-0	R-0	R-0	R-0

15 … 0
ID[15:0]
R-0

LEGEND: R = Read only; WP = Write protected (protected by busy bit); -*n* = value after reset

Table 22-39. IF3 Arbitration Register (DCAN IF3ARB) Field Descriptions

Bit	Field	Value	Description
31	MsgVal		Message Valid
		0	The message object is ignored by the message handler.
		1	The message object is to be used by the message handler.
			The CPU should reset the MsgVal bit of all unused Messages Objects during the initialization before it resets bit Init in the CAN control register. This bit must also be reset before the identifier ID[28:0], the control bits Xtd, Dir or DLC[3:0] are modified, or if the messages object is no longer required.
30	Xtd		Extended Identifier
		0	The 11-bit (“standard”) Identifier is used for this message object.
		1	The 29-bit (“extended”) Identifier is used for this message object.
29	Dir		Message Direction
		0	Direction = receive: On TxRqst, a remote frame with the identifier of this message object is transmitted. On reception of a data frame with matching identifier, this message is stored in this message object.
		1	Direction = transmit: On TxRqst, the respective message object is transmitted as a data frame. On reception of a remote frame with matching identifier, the TxRqst bit of this message object is set (if RmtEn = 1).
28-0	Msk[28:0]		Message Identifier
		ID[28:0]	29-bit Identifier (“extended frame”)
		ID[28:18]	11-bit Identifier (“standard frame”)

R-0	R-0	R-0	R-0	R-0	R-0	R-0	R-0	R-0	R-0			R-0			

LEGEND: R = Read only; -*n* = value after reset

Table 22-40. IF3 Message Control Register (DCAN IF3MCTL) Field Descriptions

Bit	Field	Value	Description
31-16	Reserved	0	These bits are always read as 0. Writes have no effect.
15	NewDat		New Data
		0	No new data has been written into the data portion of this message object by the message handler since the last time when this flag was cleared by the CPU.
		1	The message handler or the CPU has written new data into the data portion of this message object.
14	MsgLst		Message Lost (only valid for message objects with direction = receive)
		0	No message lost since the last time when this bit was reset by the CPU.
		1	The message handler stored a new message into this object when NewDat was still set, so the previous message has been overwritten.
13	IntPnd		Interrupt Pending
		0	This message object is not the source of an interrupt.
		1	This message object is the source of an interrupt. The Interrupt Identifier in the interrupt register will point to this message object if there is no other interrupt source with higher priority.
12	UMask		Use Acceptance Mask
		0	Mask ignored
		1	Use mask (Msk[28:0], MXtd, and MDir) for acceptance filtering
			If the UMask bit is set to one, the message object's mask bits have to be programmed during initialization of the message object before MsgVal is set to one.
11	TxIE		Transmit Interrupt enable
		0	IntPnd will not be triggered after the successful transmission of a frame.
		1	IntPnd will be triggered after the successful transmission of a frame.
10	RxIE		Receive Interrupt enable
		0	IntPnd will not be triggered after the successful reception of a frame.
		1	IntPnd will be triggered after the successful reception of a frame.
9	RmtEn		Remote enable
		0	At the reception of a remote frame, TxRqst is not changed.
		1	At the reception of a remote frame, TxRqst is set.
8	TxRqst		Transmit Request
		0	This message object is not waiting for a transmission.
		1	The transmission of this message object is requested and is not yet done.

22.5.27 IF3 Data A and Data B Registers (DCAN IF3DATA/DATB)

The data bytes of CAN messages are stored in the IF3 registers in the following order.

In a CAN data frame, Data 0 is the first, and Data 7 is the last byte to be transmitted or received. In CAN's serial bit stream, the MSB of each byte will be transmitted first.

The IF3 data A and data B registers (DCAN IF3DATA/DATB) are shown in Figure 22-48 and Figure 22-49.

22.5.28 Update Enable Registers (DCAN IF3UPD12 to IF3UPD78)

The automatic update functionality of the IF3 register set can be configured for each message object. A message object is enabled for automatic IF3 update, if the dedicated IF3UpdEn flag is set. This means that an active NewDat flag of this message object (e.g due to reception of a CAN frame) will trigger an automatic copy of the whole message object to IF3 register set.

The update enable registers (DCAN IF3UPD12 to IF3UPD78) are shown in Table 22-41 and described in Table 22-42.

NOTE: IF3 Update enable should not be set for transmit objects.

Table 22-41. Update Enable Registers (DCAN IF3UPD12 to IF3UPD78))

22.5.29 CAN TX I/O Control Register (DCAN TIOC)

The CAN_TX pin of the DCAN module can be used as general purpose IO pin if CAN function is not needed. The CAN TX I/O control register (DCAN TIOC) is shown in Figure 22-50 and described in Table 22-43.

NOTE: The values of the IO control registers are only writable if Init bit of the CAN control register is set.

NOTE: The OD, Func, Dir and Out bits of the CAN TX IO control register are forced to certain values when Init bit of CAN control register is reset (see bit descriptions).

Figure 22-50. CAN TX I/O Control Register (DCAN TIOC)

31	19	18	17	16
Reserved		PU	PD	OD
R-0		R/W-D	R/W-D	R/WP-0

LEGEND: R/W = Read/Write; R = Read only; WP = Protected Write (protected by Init bit), U = Undefined; D = Device dependent; -*n* = value after reset

Table 22-43. CAN TX I/O Control Register (DCAN TIOC) Field Descriptions

Bit	Field	Value	Description
31-19	Reserved	0	These bits are always read as 0. Writes have no effect.
18	PU		CAN_TX pull up/pull down select. This bit is only active when CAN_TX is configured to be an input.
		0	CAN_TX pull down is selected, when pull logic is active (PD = 0).
		1	CAN_TX pull up is selected, when pull logic is active(PD = 0).
17	PD		CAN_TX pull disable. This bit is only active when CAN_TX is configured to be an input.
		0	CAN_TX pull is active
		1	CAN_TX pull is disabled
16	OD		CAN_TX open drain enable. This bit is only active when CAN_TX is configured to be in GIO mode (TIOC.Func=0).
		0	The CAN_TX pin is configured in push/pull mode.
		1	The CAN_TX pin is configured in open drain mode.
			Forced to '0' if Init bit of CAN control register is reset.
15-4	Reserved	0	These bits are always read as 0. Writes have no effect.
3	Func		CAN_TX function. This bit changes the function of the CAN_TX pin
		0	CAN_TX pin is in GIO mode.
		1	CAN_TX pin is in functional mode (as an output to transmit CAN data).
			Forced to '1' if Init bit of CAN control register is reset.
2	Dir		CAN_TX data direction. This bit controls the direction of the CAN_TX pin when it is configured to be in GIO mode only (TIOC.Func=0)
		0	The CAN_TX pin is an input.
		1	The CAN_TX pin is an output
			Forced to '1' if Init bit of CAN control register is reset.

22.5.30 CAN RX IO Control Register (DCAN RIOC)

The CAN_RX pin of the DCAN module can be used as general purpose IO pin if CAN function is not needed. The CAN RX I/O control register (DCAN RIOC) is shown in Figure 22-51 and described in Table 22-44.

NOTE: The values of the IO control registers are writable only if Init bit of CAN control register is set.

NOTE: The OD, Func and Dir bits of the CAN RX IO control register are forced to certain values when the Init bit of CAN control register is reset (see bit descriptions).

Multichannel Serial Port Interface (McSPI)

This chapter describes the McSPI of the device.

Topic **Page**

23.1 Introduction **2856**
23.2 Integration **2856**
23.3 Functional Description **2859**
23.4 Use Cases **2894**
23.5 SPI Registers **2895**

23.1 Introduction

This document is intended to provide programmers with a functional presentation of the Master/Slave Multichannel Serial Port Interface (McSPI) module. It also provides a register description and a module configuration example.

McSPI is a general-purpose receive/transmit master/slave controller that can interface with up to four slave external devices or one single external master. It allows a duplex, synchronous, serial communication between a CPU and SPI compliant external devices (Slaves and Masters).

23.1.1 McSPI Features

The general features of the SPI controller are:

- Buffered receive/transmit data register per channel (1 word deep)
- Multiple SPI word access with one channel using a FIFO
- Two DMA requests per channel, one interrupt line
- Single interrupt line, for multiple interrupt source events
- Serial link interface supports:
  - Full duplex / Half duplex
  - Multi-channel master or single channel slave operations
  - Programmable 1-32 bit transmit/receive shift operations.
  - Wide selection of SPI word lengths continuous from 4 to 32 bits
- Up to four SPI channels
- SPI word Transmit / Receive slot assignment based on round robin arbitration
- SPI configuration per channel (clock definition, enable polarity and word width)
- Clock generation supports:
  - Programmable master clock generation (operating from fixed 48-MHz functional clock input)
  - Selectable clock phase and clock polarity per chip select.

23.1.2 Unsupported McSPI Features

This device supports only two chip selects per module. Module wakeup during slave mode operation is not supported, as noted in *McSPI Clock and Reset Management*.

Table 23-1. Unsupported McSPI Features

Feature	Reason
Chip selects 2 and 3	Not pinned out
Slave mode wakeup	SWAKEUP not connected
Retention during power down	Module not synthesized with retention enabled

23.2 Integration

This device includes two instantiations of McSPI: SPI0 and SPI1. The McSPI module is a general-purpose receive/transmit master/slave controller that can interface with either up to four slave external devices or one single external master. Figure 23-1 shows the example of a system with multiple external slave SPI compatible devices and Figure 23-2 shows the example of a system with an external master.

23.2.1 McSPI Connectivity Attributes

The general connectivity attributes for the McSPI module are shown in Table 23-2.

Table 23-2. McSPI Connectivity Attributes

Attributes	Type
Power Domain	Peripheral Domain
Clock Domain	PD_PER_L4LS_GCLK (OCP) PD_PER_SPI_GCLK (Func)
Reset Signals	PER_DOM_RST_N
Idle/Wakeup Signals	Smart Idle
Interrupt Requests	1 interrupt to MPU subsystem and PRUSS (McSPI0) 1 interrupt to MPU subsystem only (McSPI1)
DMA Requests	4 DMA requests to EDMA 1 RD & 1 WR request per CS
Physical Address	L4 Peripheral slave port

23.2.2 McSPI Clock and Reset Management

The SPI module clocks can be woken up in two manners: by the SPI module itself using the SWAKEUP signal (refer to the module functional spec for detailed conditions), or directly from an external SPI master device by detecting an active low level on its chip select input pin (CS0n) using a GPIO attached to that device pin. Neither of these methods is supported on the device.

Table 23-3. McSPI Clock Signals

Clock Signal	Max Freq	Reference / Source	Comments
CLK Interface clock	100 MHz	CORE_CLKOUTM4 / 2	pd_per_l4ls_gclk From PRCM
CLKSPIREF Functional clock	48 MHz	PER_CLKOUTM2 / 4	pd_per_spi_gclk From PRCM

23.2.3 McSPI Pin List

The McSPI interface pins are summarized in Table 23-4.

Table 23-4. McSPI Pin List

Pin	Type	Description
SPI*x*_SCLK	I/O	SPI serial clock (output when master, input when slave)
SPI*x*_D0	I/O	Can be configured as either input or output (MOSI or MISO)
SPI*x*_D1	I/O	Can be configured as either input or output (MOSI or MISO)
SPI*x*_CS0n	I/O	SPI chip select 0 output when master, input when slave (active low)
SPI*x*_CS1n	O	SPI chip select 1 output when master, input when slave (active low)

23.3 Functional Description

23.3.1 SPI Interface

This section lists the name and description of the SPI interface used for connection to external SPI compliant devices. McSPI has a total of seven external SPI signals shown in Table 23-5.

Table 23-5. McSPI Interface Pins

Pin	Type	Description
SPI_SCLK	I/O	SPI serial clock (output when master, input when slave)
SPI_D0	I/O	Can be configured as either input or output (MOSI or MISO)
SPI_D1	I/O	Can be configured as either input or output (MOSI or MISO)
$\overline{\text{SPI_CS0}}$	I/O	SPI chip select 0 output when master, input when slave (active low)
$\overline{\text{SPI_CS1}}$	I/O	SPI chip select 0 output when master, input when slave (active low)
$\overline{\text{SPI_CS2}}$	I/O	SPI chip select 2 output when master, input when slave (active low)
$\overline{\text{SPI_CS3}}$	I/O	SPI chip select 3 output when master, input when slave (active low)

23.3.2 SPI Transmission

This section describes the transmissions supported by McSPI. The SPI protocol is a synchronous protocol that allows a master device to initiate serial communication with a slave device. Data is exchanged between these devices. A slave select line (SPIEN) can be used to allow selection of an individual slave SPI device. Slave devices that are not selected do not interfere with SPI bus activities. Connected to multiple external devices, McSPI exchanges data with a single SPI device at a time through two main modes:

- Two data pins interface mode. (See Section 23.3.2.1)
- Single data pin interface mode (recommended for half-duplex transmission). (See Section 23.3.2.2)

The flexibility of McSPI allows exchanging data with several formats through programmable parameters described in Section 23.3.2.3.

23.3.2.1 Two Data Pins Interface Mode

The two data pins interface mode, allows a full duplex SPI transmission where data is transmitted (shifted out serially) and received (shifted in serially) simultaneously on separate data lines SPIDAT [0] and SPIDAT [1]. Data leaving the master exits on transmit serial data line also known as MOSI: MasterOutSlaveIn. Data leaving the slave exits on the receive data line also known as MISO: MasterInSlaveOut.

McSPI has a unified SPI port control: SPIDAT [1:0] can be independently configured as receive or transmit lines. The user has the responsibility to program which data line to use and in which direction (receive or transmit), according to the external slave/master connection.

The serial clock (SPICLK) synchronizes shifting and sampling of the information on the two serial data lines (SPIDAT [1:0]). Each time a bit is transferred out from the Master, one bit is transferred in from Slave.

Figure 23-3 shows an example of a full duplex system with a Master device on the left and a Slave device on the right. After 8 cycles of the serial clock SPICLK, the WordA has been transferred from the master to the slave. At the same time, the WordB has been transferred from the slave to the master.

When referring to the master device, the control block transmits the clock SPICLK and the enable signal SPIEN(optional depends on MCSPI_MODULECTRL[PIN34] bit field).

Figure 23-3. SPI Full-Duplex Transmission

23.3.2.2 Single Data Pin Interface Mode

In single data pin interface mode, under software control, a single data line is used to alternatively transmit and receive data (Half duplex transmission).

McSPI has a unified SPI port control: SPIDAT [1:0] can be independently configured as receive or transmit lines. The user has the responsibility to program which data line to use and in which direction (receive or transmit), according to the external slave/master connection.

As for a full duplex transmission, the serial clock (SPICLK) synchronizes shifting and sampling of the information on the single serial data line.

23.3.2.2.1 Example With a Receive-Only Slave

Figure 23-4 shows a half duplex system with a Master device on the left and a receive-only Slave device on the right. Each time a bit is transferred out from the Master, one bit is transferred in the Slave. After 8 cycles of the serial clock SPICLK, the WordA has been transferred from the master to the slave.

Figure 23-4. SPI Half-Duplex Transmission (Receive-only Slave)

23.3.2.2.2 Example With a Transmit-Only Slave

Figure 23-5 shows a half duplex system with a Master device on the left and a transmit-only Slave device on the right. Each time a bit is transferred out from the Slave, one bit is transferred in the Master. After 8 cycles of the serial clock SPICLK, the WordA has been transferred from the slave to the master.

23.3.2.3 Transfer Formats

This section describes the transfer formats supported by McSPI.

The flexibility of McSPI allows setting the parameters of the SPI transfer:

- SPI word length
- SPI enable generation programmable
- SPI enable assertion
- SPI enable polarity
- SPI clock frequency
- SPI clock phase
- SPI clock polarity

The consistency between SPI word length, clock phase and clock polarity of the master SPI device and the communicating slave device remains under software responsibility.

23.3.2.3.1 Programmable Word Length

McSPI supports any SPI word from 4 to 32 bits long.

The SPI word length can be changed between transmissions to allow a master device to communicate with peripheral slaves having different requirements.

23.3.2.3.2 Programmable SPI Enable Generation

McSPI is able to generate or not the SPI enable, if management of chip select is de-asserted a point to point connection is mandatory. Only a single master of slave device can be connected to the SPI bus.

23.3.2.3.3 Programmable SPI Enable (SPIEN)

The polarity of the SPIEN signals is programmable. SPIEN signals can be active high or low.

The assertion of the SPIEN signals is programmable: SPIEN signals can be manually asserted or can be automatically asserted.

Two consecutive words for two different slave devices may go along with active SPIEN signals with different polarity.

23.3.2.3.4 Programmable SPI Clock (SPICLK)

The phase and the polarity of the SPI serial clock are programmable when McSPI is a SPI master device or a SPI slave device. The baud rate of the SPI serial clock is programmable when McSPI is a SPI master.

When McSPI is operating as a slave, the serial clock SPICLK is an input from the master.

23.3.2.3.5 Bit Rate

In Master Mode, an internal reference clock CLKSPIREF is used as an input of a programmable divider to generate bit rate of the serial clock SPICLK. Granularity of this clock divider can be changed.

DRAFT ONLY

23.3.2.3.6 Polarity and Phase

McSPI supports four sub-modes of the SPI format transfer that depend on the polarity (POL) and the phase (PHA) of the SPI serial clock (SPICLK). Table 23-6 and Figure 23-6 show a summary of the four sub-modes. Software selects one of four combinations of serial clock phase and polarity.

Two consecutive SPI words for two different slave devices may go along with active SPICLK signal with different phase and polarity.

Table 23-6. Phase and Polarity Combinations

Polarity (POL)	Phase (PHA)	SPI Mode	Comments
0	0	mode0	SPICLK active high and sampling occurs on the rising edge.
0	1	mode1	SPICLK active high and sampling occurs on the falling edge.
1	0	mode2	SPICLK active low and sampling occurs on the falling edge.
1	1	mode3	SPICLK active low and sampling occurs on the rising edge.

Figure 23-6. Phase and Polarity Combinations

23.3.2.3.7 Transfer Format With PHA = 0

This section describes the concept of a SPI transmission with the SPI mode0 and the SPI mode2.

In the transfer format with PHA = 0, SPIEN is activated a half cycle of SPICLK ahead of the first SPICLK edge.

In both master and slave modes, McSPI drives the data lines at the time of SPIEN is asserted.

Each data frame is transmitted starting with the MSB. At the extremity of both SPI data lines , the first bit of SPI word is valid a half cycle of SPICLK after the SPIEN assertion.

Therefore, the first edge of the SPICLK line is used by the master to sample the first data bit sent by the slave. On the same edge, the first data bit sent by the master is sampled by the slave.

On the next SPICLK edge, the received data bit is shifted into the shift register, and a new data bit is transmitted on the serial data line.

This process continues for a total of pulses on the SPICLK line defined by the SPI word length programmed in the master device, with data being latched on odd numbered edges and shifted on even numbered edges.

Figure 23-7 is a timing diagram of a SPI transfer for the SPI mode0 and the SPI mode2, when McSPI is master or slave, with the frequency of SPICLK equals to the frequency of CLKSPIREF. It should not be used as a replacement for SPI timing information and requirements detailed in [3].

When McSPI is in slave mode, if the SPIEN line is not de-asserted between successive transmissions then the content of the Transmitter register is not transmitted, instead the last received SPI word is transmitted.

In master mode, the SPIEN line must be negated and reasserted between each successive SPI word. This is because the slave select pin freezes the data in its shift register and does not allow it to be altered if PHA bit equals 0.

In 3-pin mode without using the SPIEN signal, the controller provides the same waveform but with SPIEN forced to low state. In slave mode SPIEN is useless

Figure 23-7. Full Duplex Single Transfer Format with PHA = 0

23.3.2.3.8 Transfer Format With PHA = 1

This section describes SPI full duplex transmission with the SPI mode1 and the SPI mode3.

In the transfer format with PHA = 1, SPIEN is activated a delay (t_{Lead}) ahead of the first SPICLK edge.

In both master and slave modes, McSPI drives the data lines on the first SPICLK edge.

Each data frame is transmitted starting with the MSB. At the extremity of both SPI data lines , the first bit of SPI word is valid on the next SPICLK edge, a half cycle of SPICLK later. It is the sampling edge for both the master and slave.

When the third edge occurs, the received data bit is shifted into the shift register. The next data bit of the master is provided to the serial input pin of the slave.

This process continues for a total of pulses on the SPICLK line defined by the word length programmed in the master device, with data being latched on even numbered edges and shifted on odd numbered edges.

Figure 23-8 is a timing diagram of a SPI transfer for the SPI mode1 and the SPI mode3, when McSPI is master or slave, with the frequency of SPICLK equals to the frequency of CLKSPIREF. It should not be used as a replacement for SPI timing information and requirements detailed in [3].

The SPIEN line may remain active between successive transfers. In 3-pin mode without using the SPIEN signal, the controller provides the same waveform but with SPIEN forced to low state. In slave mode SPIEN is useless.

23.3.3 Master Mode

McSPI is in master mode when the bit MS of the register MCSPI_MODULCTRL is cleared.

In master mode McSPI supports multi-channel communication with up to 4 independent SPI communication channel contexts. McSPI initiates a data transfer on the data lines (SPIDAT [1;0]) and generates clock (SPICLK) and control signals (SPIEN) to a single SPI slave device at a time.

23.3.3.1 Dedicated Resources Per Channel

In the following sections, the letter “I” indicates the channel number that can be 0, 1, 2 or 3. Each channel has the following dedicated resources:

- Its own channel enable, programmable with the bit EN of the register MCSPI_CH(I)CTRL. Disabling the channel, outside data word transmission, remains under user responsibility.
- Its own transmitter register MCSPI_TX on top of the common shift register. If the transmitter register is empty, the status bit TXS of the register MCSPI_CH(I)STAT is set.
- Its own receiver register MCSPI_RX on top of the common shift register. If the receiver register is full, the status bit RXS of the register MCSPI_CH(I)STAT is set.
- A fixed SPI ENABLE line allocation (SPIEN[i] port for channel “I”), SPI enable management is optional.
- Its own communication configuration with the following parameters via the register (I)CONF
  - Transmit/Receive modes, programmable with the bit TRM.
  - Interface mode (Two data pins or Single data pin) and data pins assignment, both programmable with the bits IS and DPE.
  - SPI word length, programmable with the bits WL.
  - SPIEN polarity, programmable with the bit EPOL.
  - SPIEN kept active between words, programmable with the bit FORCE.
  - Turbo mode, programmable with the bit TURBO.
  - SPICLK frequency, programmable with the bit CLKD, the granularity of clock division can be changed using CLKG bit, the clock ratio is then concatenated with MCSPI_CHCTRL[EXTCLK] value.
  - SPICLK polarity, programmable with the bit POL
  - SPICLK phase, programmable with the bit PHA.
  - Start bit extension enable, programmable with the bit SBE to support LoSSI transfer specification [4].
  - Start bit polarity, programmable with the bit SBPOL
  - Use a FIFO Buffer or not( ), programmable with FFER and FFEW, depending on transfer mode TRM.
- Two DMA requests events, read and write, to synchronize read/write accesses of the DMA controller with the activity of McSPI. The DMA requests are enabled with the bits DMAR and DMAW.
- Three interrupts events

The transfers will use the latest loaded parameters of the register (I)CONF.

The configuration parameters SPIEN polarity, Turbo mode, SPICLK phase and SPICLK polarity can be loaded in the (I)CONF register only when the channel is disabled. The user has the responsibility to change the other parameters of the (I)CONF register when no transfer occurs on the SPI interface.

Copyright © 2011, Texas Instruments Incorporated

23.3.3.2 Interrupt Events in Master Mode

In master mode, the interrupt events related to the transmitter register state are TX_empty and TX_underflow. The interrupt event related to the receiver register state is RX_full.

23.3.3.2.1 TX_empty

The event TX_empty is activated when a channel is enabled and its transmitter register becomes empty (transient event). Enabling channel automatically raises this event, except for the Master receive only mode. (See Section 23.3.3.5). When FIFO buffer is enabled (MCSPI_CH(I)CONF[FFEW] set to 1), the TX_empty is asserted as soon as there is enough space in buffer to write a number of byte defined by MCSPI_XFERLEVEL[AEL].

Transmitter register must be loaded to remove the source of the interrupt and the TX_empty interrupt status bit must be cleared for interrupt line de-assertion (if event enabled as interrupt source) . (See Section 23.3.5).

When FIFO is enabled, no new TX_empty event will be asserted as soon as CPU has not performed the number of write into transmitter register defined by MCSPI_XFERLEVEL[AEL]. It is the responsibility of CPU to perform the right number of writes.

23.3.3.2.2 TX_underflow

The event TX_underflow is activated when the channel is enabled and if the transmitter register or FIFO is empty (not updated with new data) at the time of shift register assignment.

The TX_underflow is a harmless warning in master mode.

To avoid having TX_underflow event at the beginning of a transmission, the event TX_underflow is not activated when no data has been loaded into the transmitter register since channel has been enabled.

To avoid having TX_underflow event the Transmitter register must be loaded seldom.

TX_underflow interrupt status bit must be cleared for interrupt line de-assertion (if event enable as interrupt source).

Note: Be careful, when more than one channel have a FIFO enable bit field FFER or FFEW set, the module force no use of FIFO, software must take care that only one enabled channel is configured to use the FIFO buffer.

23.3.3.2.3 RX_ full

The event RX_full is activated when channel is enabled and receiver register becomes filled (transient event). When FIFO buffer is enabled (MCSPI_CH(I)CONF[FFER] set to 1), the RX_full is asserted as soon as there is a number of bytes holds in buffer to read defined by MCSPI_XFERLEVEL[AFL].

Receiver register must be read to remove source of interrupt and RX_full interrupt status bit must be cleared for interrupt line de-assertion (if event enabled as interrupt source).

When FIFO is enabled, no new RX_full event will be asserted as soon as CPU has not performed the number of read into receive register defined by MCSPI_XFERLEVEL[AFL]. It is the responsibility of CPU to perform the right number of reads.

23.3.3.2.4 End of Word Count

The event end of word count (EOW) is activated when channel is enabled and configured to use the built-in FIFO. This interrupt is raised when the controller had performed the number of transfer defined in MCSPI_XFERLEVEL[WCNT] register. If the value was programmed to 0000h, the counter is not enabled and this interrupt is not generated.

The End of Word count interrupt also indicates that the SPI transfer is halt on channel using the FIFO buffer as soon as MCSPI_XFERLEVEL[WCNT] is not reloaded and channel re-enabled.

End of Word interrupt status bit must be cleared for interrupt line de-assertion (if event enable as interrupt source).

23.3.3.3 Master Transmit and Receive Mode

This mode is programmable per channel (bits TRM of the register (I)CONF).

The channel access to the shift registers, for transmission/reception, is based on its transmitter and receiver register state and round robin arbitration.

The channel that meets the rules below is included in the round robin list of already active channels scheduled for transmission and/or reception. The arbiter skips the channel that does not meet the rules and search for the next following enabled channel, in rotation.

Rule 1: Only enabled channels (bit EN of the register MCSPI_CH(I)CTRL), can be scheduled for transmission and/or reception.

Rule 2: An enabled channel can be scheduled if its transmitter register is not empty (bit TXS of the register MCSPI_CH(I)STAT) or its FIFO is not empty in case of buffer use for the corresponding channel (bit FFE of the register MCSPI_CH(I)STAT), that is updated with new data, at the time of shift register assignment. If the transmitter register or FIFO is empty, at the time of shift register assignment, the event TX_underflow is activated and the next enabled channel with new data to transmit is scheduled. (See also transmit only mode).

Rule 3: An enabled channel can be scheduled if its receive register is not full (bit RXS of the register MCSPI_CH(I)STAT)) or its FIFO is not full in case of buffer use for the corresponding channel (bit FFF of the register MCSPI_CH(I)STAT) at the time of shift register assignment. (See also receive only mode). Therefore the receiver register of FIFO cannot be overwritten. The RX_overflow bit, in the MCSPI_IRQSTATUS register is never set in this mode.

On completion of SPI word transfer (bit EOT of the register MCSPI_CH(I)STAT is set) the updated transmitter register of the next scheduled channel is loaded into the shift register. This bit is meaningless when using the Buffer for this channel. The serialization (transmit and receive) starts according to the channel communication configuration. On serialization completion the received data is transferred to the channel receive register.

The built-in FIFO is available in this mode and can be configured in one data direction Transmit or Receive, then the FIFO is seen as a unique FFNBYTE bytes buffer, or it can also be configured in both data direction Transmit and Receive, then the FIFO is split into two separate FFNBYTE/2 bytes buffer with their own address space management, in this last case the definition of AEL and AFL levels is based on FFNBYTE/2 bytes and is under CPU responsibility.

23.3.3.4 Master Transmit-Only Mode

This mode avoids the CPU to read the receiver register (minimizing data movement) when only transmission is meaningful.

The master transmit only mode is programmable per channel (bits TRM of the register (I)CONF).

In master transmit only mode, transmission starts after data is loaded into the transmitter register.

Rule 1 and **Rule 2**, defined above, are applicable in this mode.

Rule 3, defined above, is not applicable: In master transmit only mode, the receiver register or FIFO state “full” does not prevent transmission, and the receiver register is always overwritten with the new SPI word. This event in the receiver register is not significant when only transmission is meaningful. So, the RX_overflow bit, in the MCSPI_IRQSTATUS register is never set in this mode.

The McSPI module automatically disables the RX_full interrupt status. The corresponding interrupt request and DMA Read request are not generated in master transmit only mode.

The status of the serialization completion is given by the bit EOT of the register MCSPI_CH(I)STAT. This bit is meaningless when using the Buffer for this channel.

The built-in FIFO is available in this mode and can be configured with FFEW bit field in the MCSPI_CH(I)CONF register, then the FIFO is seen as a unique FFNBYTE bytes buffer.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

23.3.3.5 Master Receive-Only Mode

This mode avoids the CPU to refill the transmitter register (minimizing data movement) when only reception is meaningful.

The master receive mode is programmable per channel (bits TRM of the register (I)CONF).

The master receive only mode enables channel scheduling only on empty state of the receiver register.

Rule 1 and **Rule 3**, defined above, are applicable in this mode.

Rule 2, defined above, is not applicable: In master receive only mode, after the first loading of the transmitter register of the enabled channel, the transmitter register state is maintained as full. The content of the transmitter register is always loaded into the shift register, at the time of shift register assignment. So, after the first loading of the transmitter register, the bits TX_empty and TX_underflow, in the MCSPI_IRQSTATUS register are never set in this mode.

The status of the serialization completion is given by the bit EOT of the register MCSPI_CH(I)STAT. The bit RX_full in the MCSPI_IRQSTATUS register is set when a received data is loaded from the shift register to the receiver register. This bit is meaningless when using the Buffer for this channel.

The built-in FIFO is available in this mode and can be configured with FFER bit field in the MCSPI_CH(I)CONF register, then the FIFO is seen as a unique FFNBYTE bytes buffer.

23.3.3.6 Single-Channel Master Mode

When the SPI is configured as a master device with a single enabled channel, the assertion of the SPIM_CSX signal can be controlled in two different ways:

- In 3 pin mode : MCSPI_MODULCTRL[1] PIN34 and MCSPI_MODULCTRL[0] SINGLE bit are set to 1, the controller transmit SPI word as soon as transmit register or FIFO is not empty.
- In 4 pin mode : MCSPI_MODULCTRL[1] PIN34 bit is cleared to 0 and MCSPI_MODULCTRL[0] SINGLE bit is set to 1, SPIEN assertion/deassertion controlled by Software. (See Section 23.3.3.6.1) using the MCSPI_CHxCONF[20] FORCE bit.

23.3.3.6.1 Programming Tips When Switching to Another Channel

When a single channel is enabled and data transfer is ongoing:

- Wait for completion of the SPI word transfer (bit EOT of the register MCSPI_CH(I)STAT is set) before disabling the current channel and enabling a different channel.
- Disable the current channel first, and then enable the other channel.

23.3.3.6.2 Keep SPIEN Active Mode (Force SPIEN)

Continuous transfers are manually allowed by keeping the SPIEN signal active for successive SPI words transfer. Several sequences (configuration/enable/disable of the channel) can be run without deactivating the SPIEN line. This mode is supported by all channels and any master sequence can be used (transmit-receive, transmit-only, receive-only).

Keeping the SPIEN active mode is supported when:

- A single channel is used (bit MCSPI_MODULCTRL[Single] is set to 1).
- Transfer parameters of the transfer are loaded in the configuration register (MCSPI_CH(I)CONF) in the appropriate channel.

  The state of the SPIEN signal is programmable.
  - Writing 1 into the bit FORCE of the register MCSPI_CH(I)CONF drives high the SPIEN line when MCSPI_CHCONF(I)[EPOL] is set to zero, and drives it low when MCSPI_CHCONF(I)[EPOL] is set.
  - Writing 0 into the bit FORCE of the register MCSPI_CH(I)CONF drives low the SPIEN line when MCSPI_CHCONF(I)[EPOL] is set to zero, and drives it high when MCSPI_CHCONF(I)[EPOL] is set.
- A single channel is enabled (MCSPI_CH(I)CTRL[En] set to 1) . The first enabled channel activates the SPIEN line.

Copyright © 2011, Texas Instruments Incorporated

Once the channel is enabled, the SPIEN signal is activated with the programmed polarity.

As in multi-channel master mode, the start of the transfer depends on the status of the transmitter register, the status of the receiver register and the mode defined by the bits TRM in the configuration register (transmit only, receive only or transmit and receive) of the enabled channel.

The status of the serialization completion of each SPI word is given by the bit EOT of the register MCSPI_CH(I)STAT. The bit RX_full in the MCSPI_IRQSTATUS register is set when a received data is loaded from the shift register to the receiver register.

A change in the configuration parameters is propagated directly on the SPI interface. If the SPIEN signal is activated the user must insure that the configuration is changed only between SPI words, in order to avoid corrupting the current transfer.

NOTE: The SPIEN polarity, the SPICLK phase and SPICLK polarity must not be modified when the SPIEN signal is activated. The Transmit/Receive mode, programmable with the bit TRM can be modified only when the channel is disabled. The channel can be disabled and enabled while the SPIEN signal is activated.

The delay between SPI words that requires the connected SPI slave device to switch from one configuration (Transmit only for instance) to another (receive only for instance) must be handled under software responsibility.

At the end of the last SPI word, the channel must be deactivated (MCSPI_CH(I)CTRL[En] is cleared to 0) and the SPIEN can be forced to its inactive state (MCSPI_CH(I)CONF[Force]).

Figure 23-9 and Figure 23-10 show successive transfers with SPIEN kept active low with a different configuration for each SPI word in respectively single data pin interface mode and two data pins interface mode. The arrows indicate when the channel is disabled before a change in the configuration parameters and enabled again.

Figure 23-9. Continuous Transfers With SPIEN Maintained Active (Single-Data-Pin Interface Mode)

Figure 23-10. Continuous Transfers With SPIEN Maintained Active (Dual-Data-Pin Interface Mode)

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

NOTE: The turbo mode is also supported for the Keep SPIEN active mode when the following conditions are met:

- A single channel will be explicitly used (bit MCSPI_MODULCTRL[Single] is set to 1).
- The turbo mode is enabled in the configuration of the channel (bit Turbo of the register (i)CONF).

23.3.3.6.3 Turbo Mode

The purpose of the Turbo mode is to improve the throughput of the SPI interface when a single channel is enabled, by allowing transfers until the shift register and the receiver register are full.

This mode is programmable per channel (bit Turbo of the register (I)CONF). When several channels are enabled, the bit Turbo of the registers MCSPI_CH(I)CONF has no effect, and the channel access to the shift registers remains as described in Section 23.3.3.3.

In Turbo mode, **Rule 1** and **Rule 2** defined in Section 23.3.3.3 are applicable but Rule 3 is not applicable. An enabled channel can be scheduled if its receive register is full (bit RXS of the register MCSPI_CH(I)STAT) at the time of shift register assignment until the shift register is full.

In Turbo mode, **Rule 1** and **Rule 2** defined in Section 23.3.3.3 are applicable but Rule 3 is not applicable. An enabled channel can be scheduled if its receive register is full (bit RXS of the register MCSPI_CH(I)STAT) at the time of shift register assignment until the shift register is full.

The receiver register cannot be overwritten in turbo mode. In consequence the RX_overflow bit, in MCSPI_IRQSTATUS register is never set in this mode.

23.3.3.7 Start Bit Mode

The purpose of the start bit mode is to add an extended bit before the SPI word transmission specified by word length WL. This feature is only available in master mode. This mode is compliant with write command/data format as specified in LoSSI protocol.

This mode is programmable per channel (bit Start bit enable SBE of the register MCSPI_CH(I)CONF).

The polarity of the extended bit is programmable per channel and it indicates whether the next SPI word must be handled as a command when SBPOL is cleared to 0 or as a data or a parameter when SBPOL is set to 1 (refer to LoSSI specification [4]). Moreover start bit polarity SBPOL can be changed dynamically during start bit mode transfer without disabling the channel for reconfiguration, in this case you have the responsibility to configure the SBPOL bit before writing the SPI word to be transmitted in TX register.

The start bit mode could be used at the same time as turbo mode and/or manual chip select mode. In this case only one channel could be used, no round-robin arbitration is possible.

23.3.3.8 Chip-Select Timing Control

The chip select timing control is only available in master mode with automatic chip select generation (FORCE bit field is cleared to 0), to add a programmable delay between chip select assertion and first clock edge or chip select removal and last clock edge. The option is available only in 4 pin mode MCSPI_MODULCTRL[1] PIN34 is cleared to 0.

This mode is programmable per channel (bit TCS of the register MCSPI_CH(I)CONF). Figure 23-12 shows the chip-select SPIEN timing control.

Figure 23-12. Chip-Select SPIEN Timing Controls

NOTE: Because of the design implementation for transfers using a clock divider ratio set to 1 (clock bypassed), a half cycle must be added to the value between chip-select assertion and the first clock edge with PHA = 1 or between chip-select removal and the last clock edge with PHA = 0.

With an odd clock divider ratio which occurs when granularity is one clock cycle, that means that MCSPI_CH(I)CONF[CLKG] is set to 1 and MCSPI_CH(I)CONF[CLKD] has an even value, the clock duty cycle is not 50%, then one of the high level or low level duration is selected to be added to TCS delay.

Table 23-7 summarizes all delays between chip select and first (setup) or last (hold) clock edge.

In 3-pin mode this option is useless, the chip select SPIEN is forced to low state.

Table 23-7. Chip Select ↔ Clock Edge Delay Depending on Configuration

Clock Ratio F_{ratio}	Clock Phase PHA	Chip Select ↔ Clock Edge Delay	
		Setup	Hold
1	0	T_ref × (TCS + ½)	T_ref × (TCS + 1)
	1	T_ref × (TCS + 1)	T_ref × (TCS + ½)
Even ≥ 2	x	T_ref × F_{ratio} × (TCS + ½)	T_ref × F_{ratio} × (TCS + ½)
Odd ≥ 3 (only with MCSPI_CH(I)CONF[CLKG] set to 1	0	T_ref × [{F_{ratio} × TCS) + (F_{ratio} + ½)]	T_ref × [{F_{ratio} × TCS) + (F_{ratio} + ½)]
	1	T_ref × [{F_{ratio} × TCS) + (F_{ratio} - ½)]	T_ref × [{F_{ratio} × TCS) + (F_{ratio} - ½)]

T_ref = CLKSPIREF period in ns. F_{ratio} = SPI clock division ratio

The clock divider ratio depends on divider granularity MCSPI_CH(I)CONF[CLKG]:

- MCSPI_CH(I)CONF[CLKG] = 0 : granularity is power of two.
  $F_{ratio} = 2^{MCSPI_CH(I)CONF[CLKD]}$

23.3.3.9 Clock Ratio Granularity

By default the clock division ratio is defined by the register MCSPI_CH(I)CONF[CLKD] with power of two granularity leading to a clock division in range 1 to 32768, in this case the duty cycle is always 50%. With bit MCSPI_CH(I)CONF[CLKG] the clock division granularity can be changed to one clock cycle, in that case the register MCSPI_CH(I)CTRL[EXTCLK] is concatenated with MCSPI_CH(I)CONF[CLKD] to give a 12-bit width division ratio in range 1 to 4096.

When granularity is one clock cycle (MCSPI_CH(I)CONF[CLKG] set to 1), for odd value of clock ratio the clock duty cycle is kept to 50-50 using falling edge of clock reference CLKSPIREF.

Table 23-8. CLKSPIO High/Low Time Computation

Clock Ratio F_{ratio}	CLKSPIO High Time	CLKSPIO Low Time
1	T_{high}_ref	T_{low}_ref
Even ≥ 2	t_ref × (F_{ratio}/2)	t_ref × (F_{ratio}/2)
Odd ≥ 3	t_ref × (F_{ratio}/2)	t_ref × (F_{ratio}/2)

T_ref = CLKSPIREF period in ns. T_{high}_ref = CLKSPIREF high Time period in ns. T_{low}_ref = CLKSPIREF low Time period in ns. F_{ratio} = SPI clock division ratio

F_{ratio} = MCSPI_CH(I)CTRL[EXTCLK].MCSPI_CH(I)CONF[CLKD] + 1

For odd ratio value the duty cycle is calculated as below:

Duty_cycle = ½

Granularity examples: With a clock source frequency of 48 MHz:

Table 23-9. Clock Granularity Examples

MCSPI_CH (I)CTRL	MCSPI_CH (I)CONF	MCSPI_CH (I)CONF		MCSPI_CH (I)CONF	MCSPI_CH (I)CONF	Thigh (ns)	Tlow (ns)	Tperiod (ns)	Duty Cycle	Fout (MHz)

23.3.3.10 FIFO Buffer Management (Optional USEFIFO = 1)

The McSPI controller has a built-in FFNBYTE bytes buffer in order to unload DMA or interrupt handler and improve data throughput. The instantiation of this Buffer is optional it depends on a generic parameter USEFIFO, the FIFO is instantiated when it is set to 1. Allowed FIFO depth up to 64 bytes is supported and is defined by generic parameter FFNBYTE. When the FIFO is not instantiated writes in registers MCSPI_XFERLEVEL, MCSPI_CH(I)CONF[FFER] and MCSPI_CH(I)CONF[FFEW] have no functional effect, nevertheless read back is allowed to check written value.

This buffer can be used by only one channel at once and is selected by setting MCSPI_CH(I)CONF[FFER] or MCSPI_CH(I)CONF[FFEW] to 1.

If several channel are selected and several FIFO enable bitfields set to 1, the controller forces buffer not to be used, it is the responsibility of the driver to set only one FIFO enable bitfield.

The buffer can be used in the modes defined below:

- Master or Slave mode.
- Transmit only, Receive only or Transmit/Receive mode.
- Single channel or turbo mode, or in normal round robin mode. In round robin mode the buffer is used by only one channel.
- Every word length MCSPI_CH(I)CONF[WL] are supported.

Two levels AEL and AFL located in MCSPI_XFERLEVEL register rule the buffer management. The granularity of these levels is one byte, then it is not aligned with SPI word length. It is the responsibility of the driver to set these values as a multiple of SPI word length defined in MCSPI_CH(I)CONF[WL]. The number of byte written in the FIFO depends on word length (see Table 23-10).

Table 23-10. FIFO Writes, Word Length Relationship

	SPI Word Length WL		
	3 ≤ WL ≤ 7	**8 ≤ WL ≤ 15**	**16 ≤ WL ≤ 31**
Number of byte written in the FIFO	1 byte	2 bytes	4 byte

23.3.3.10.1 Splitted FIFO

The FIFO can be splitted into two part when module is configured in transmit/receive mode MCSPI_CH(I)CONF[TRM] is cleared to 0 and MCSPI_CH(I)CONF[FFER] and MCSPI_CH(I)CONF[FFEW] asserted. Then system can access a FFNBYTE/2 byte depth FIFO per direction.

The FIFO buffer pointers are reset when the corresponding channel is enabled or FIFO configuration changes.

23.3.3.10.2 Buffer Almost Full

The bitfield MCSPI_XFERLEVEL[AFL] is needed when the buffer is used to receive SPI word from a slave (MCSPI_CH(I)CONF[FFER] must be set to 1) and register width depends on the generic parameter FFNBYTE value. It defines the almost full buffer status.

When FIFO pointer reaches this level an interrupt or a DMA request is sent to the CPU to enable system to read AFL+1 bytes from receive register. Be careful AFL+1 must correspond to a multiple value of MCSPI_CH(I)CONF[WL].

When DMA is used, the request is de-asserted after the first receive register read.

No new request will be asserted again as long as system has not performed the right number of read accesses.

Figure 23-19. Buffer Almost Full Level (AFL)

* non-DMA mode only. In DMA mode, the DMA RX request is asserted to its active level under identical conditions.

.

NOTE: SPI_IRQSTATUS register bits are not available in DMA mode. In DMA mode, the SPIm_DMA_RX*n* request is asserted on the same conditions than the SPI_IRQSTATUS RX*n*_FULL flag.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

23.3.3.10.3 Buffer Almost Empty

The bitfield MCSPI_XFERLEVEL[AEL] is needed when the buffer is used to transmit SPI word to a slave (MCSPI_CH(I)CONF[FFEW]must be set to 1) and register width depends on the generic parameter FFNBYTE value. It defines the almost empty buffer status.

When FIFO pointer has not reached this level an interrupt or a DMA request is sent to the CPU to enable system to write AEL+1 bytes to transmit register. Be careful AEL+1 must correspond to a multiple value of MCSPI_CH(I)CONF[WL].

When DMA is used, the request is de-asserted after the first transmit register write.

No new request will be asserted again as long as system has not performed the right number of write accesses.

Figure 23-20. Buffer Almost Empty Level (AEL)

* non-DMA mode only. In DMA mode, the DMA TX request is asserted to its active level under identical conditions.

.

23.3.3.10.4 End of Transfer Management

When the FIFO buffer is enabled for a channel, the user shall previously configure the MCSPI_XFERLEVEL register the AEL and AFL levels and especially the WCNT bit field to define the number of Spi word to be transferred using the FIFO before enabling the channel.

This counter allows the controller to stop the transfer correctly after a defined number of Spi word transfer. If WNCT is cleared to 0, the counter is not used and the user must stop the transfer manually by disabling the channel, in this case the user doesn't know how many SPI transfers have been done. For receive transfer, software shall poll the corresponding FFE bit field and read the Receive register to empty the FIFO buffer.

When End Of Word count interrupt is generated, the user can disable the channel and poll on MCSPI_CH(I)STAT[FFE] register to know if SPI word is still there in FIFO buffer and read last words.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

23.3.3.10.5 Multiple SPI Word Access

The CPU has the ability to perform multiple SPI word access to the receive or transmit registers within a single 32-bit OCP access by setting the bit field MCSPI_MODULCTRL[MOA] to '1' under specific conditions:

- The channel selected has the FIFO enable.
- Only FIFO sense enabled support the kind of access.
- The bit field MCSPI_MODULCTRL[MOA] is set to 1
- Only 32-bit OCP access and data width can be performed to receive or transmit registers, for other kind of access the CPU must de-assert MCSPI_MODULCTRL[MOA] bit fields.
- The Level MCSPI_XFERLEVEL[AEL] and MCSPI_XFERLEVEL[AFL] must be 32-bit aligned , it means that AEL[0] = AEL[1] = 1 or AFL[0] = AFL[1] = 1.
- If MCSPI_XFERLEVEL[WCNT] is used it must be configured according to SPI word length.
- The word length of SPI words allows to perform multiple SPI access, that means that MCSPI_CH(I)CONF[WL] < 16

Number of SPI word access depending on SPI word length:

- 3 ≤ WL ≤ 7, SPI word length smaller or equal to byte length, four SPI words accessed per 32-bit OCP read/write. If word count is used (MCSPI_XFERLEVEL[WCNT]), set the bit field to WCNT[0]=WCNT[1]=0
- 8 ≤ WL ≤ 15, SPI word length greater than byte or equal to 16-bit length, two SPI words accessed per 32-bit OCP read/write. If word count is used (MCSPI_XFERLEVEL[WCNT]), set the bit field to WCNT[0]= 0.
- 16 ≤ WL multiple SPI word access not applicable.

23.3.3.11 First SPI Word Delayed

The McSpi controller has the ability to delay the first SPI word transfer to give time for system to complete some parallel processes or fill the FIFO in order to improve transfer bandwidth. This delay is applied only on first SPI word after SPI channel enabled and first write in Transmit register. It is based on output clock frequency.

This option is meaningful in master mode and single channel mode MCSPI_MODULECTRL[SINGLE] asserted.

Figure 23-21. Master Single Channel Initial Delay

Few delay values are available: No delay, 4/8/16/32 Spi cycles.

Its accuracy is half cycle in clock bypass mode and depends on clock polarity and phase.

Copyright © 2011, Texas Instruments Incorporated

23.3.3.12 3- or 4-Pin Mode

External SPI bus interface can be configured to use a restricted set of pin using the bit field MCSPI_MODULCTRL[1] PIN34 and depending on targeted application:

- If MCSPI_MODULECTRL[34] is cleared to 0 (default value) the controller is in 4-pin mode using the SPI pins CLKSPI, SOMI, SIMO and chip enable CS.
- If MCSPI_MODULECTRL[34] is set to 1 the controller is in 3-pin mode using the SPI pins CLKSPI, SOMI and SIMO.

In this mode it is mandatory to put the controller in single channel master mode (MCSPI_MODULECTRL[SINGLE] asserted) and to connect only one SPI device on the bus.

Figure 23-22. 3-Pin Mode System Overview

In 3-pin mode all options related to chip select management are useless:

- MCSPI_CHxCONF[EPOL]
- MCSPI_CHxCONF[TCS0]
- MCSPI_CHxCONF[FORCE]

The chip select pin SPIEN is forced to ‘0’ in this mode.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

23.3.4 Slave Mode

McSPI is in slave mode when the bit MS of the register MCSPI_MODULCTRL is set.

In slave mode, McSPI can be connected to up to 4 external SPI master devices. McSPI handles transactions with a single SPI master device at a time.

In slave mode, McSPI initiates data transfer on the data lines (SPIDAT[1;0]) when it receives an SPI clock (SPICLK) from the external SPI master device.

The controller is able to work with or without a chip select SPIEN depending on MCSPI_MODULCTRL[1] PIN34 bit setting. It also support transfers without dead cycle between two successive words.

23.3.4.1 Dedicated Resources

In slave mode, enabling a channel that is not channel 0 has no effect. Only channel 0 can be enabled. The channel 0, in slave mode has the following resources:

- Its own channel enable, programmable with the bit EN of the register MCSPI_CH0CTRL. This channel should be enabled before transmission and reception. Disabling the channel, outside data word transmission, remains under user responsibility.
- Any of the 4 ports SPIEN[3:0] can be used as a slave SPI device enable. This is programmable with the bits SPIENSLV of the register MCSPI_CH0CONF.
- Its own transmitter register MCSPI_TX on top of the common shift register. If the transmitter register is empty, the status bit TXS of the register MCSPI_CH0STAT is set. When McSPI is selected by an external master (active signal on the SPIEN port assigned to channel 0), the transmitter register content of channel0 is always loaded in shift register whether it has been updated or not. The transmitter register should be loaded before McSPI is selected by a master.
- Its own receiver register MCSPI_RX on top of the common shift register. If the receiver register is full, the status bit RXS of the register MCSPI_CH0STAT is set.

NOTE: The transmitter register and receiver registers of the other channels are not used. Read from or Write in the registers of a channel that is not channel 0 has no effect.

- Its own communication configuration with the following parameters via the register MCSPI_CH0CONF:
  - Transmit/Receive modes, programmable with the bit TRM.
  - Interface mode (Two data pins or Single data pin) and data pins assignment, both programmable with the bits IS and DPE.
  - SPI word length, programmable with the bits WL.
  - SPIEN polarity, programmable with the bit EPOL.
  - SPICLK polarity, programmable with the bit POL.
  - SPICLK phase, programmable with the bit PHA.
  - Use a FIFO buffer or not, programmable with FFER and FFEW, depending on transfer mode TRM.

The SPICLK frequency of a transfer is controlled by the external SPI master connected to McSPI. The bits CLKD0 of the register 0CONF are not used in slave mode.

NOTE: The configuration of the channel can be loaded in the 0CONF register only when the channel is disabled.

- Two DMA requests events, read and write, to synchronize read/write accesses of the DMA controller with the activity of McSPI. The DMA requests are enabled with the bits DMAR and DMAW of the register 0CONF.
- Four interrupts events.

Figure 23-23 shows an example of four slaves wired on a single master device.

Copyright © 2011, Texas Instruments Incorporated

Figure 23-23. Example of SPI Slave with One Master and Multiple Slave Devices on Channel 0

23.3.4.2 Interrupt Events in Slave Mode

The interrupt events related to the transmitter register state are TX_empty and TX_underflow. The interrupt events related to the receiver register state are RX_full and RX_overflow.

23.3.4.2.1 TX_EMPTY

The event TX_empty is activated when the channel is enabled and its transmitter register becomes empty. Enabling channel automatically raises this event. When FIFO buffer is enabled (MCSPI_CH(I)CONF[FFEW] set to 1), the TX_empty is asserted as soon as there is enough space in buffer to write a number of byte defined by MCSPI_XFERLEVEL[AEL].

Transmitter register must be load to remove source of interrupt and TX_empty interrupt status bit must be cleared for interrupt line de-assertion (if event enable as interrupt source).

When FIFO is enabled, no new TX_empty event will be asserted as soon as Local Host has not performed the number of write into transmitter register defined by MCSPI_XFERLEVEL[AEL]. It is the responsibility of Local Host to perform the right number of writes.

Copyright © 2011, Texas Instruments Incorporated

23.3.4.2.2 TX_UNDERFLOW

The event TX_underflow is activated when channel is enabled and if the transmitter register or FIFO (if use of buffer is enabled) is empty (not updated with new data) when an external master device starts a data transfer with McSPI (transmit and receive).

When FIFO is enabled the data emitted while underflow event is raised is not the last data written in the FIFO.

The TX_underflow indicates an error (data loss) in slave mode.

To avoid having TX_underflow event at the beginning of a transmission, the event TX_underflow is not activated when no data has been loaded into the transmitter register since channel has been enabled.

TX_underflow interrupt status bit must be cleared for interrupt line de-assertion (if event enable as interrupt source).

23.3.4.2.3 RX_FULL

The event RX_full is activated when channel is enabled and receiver becomes filled (transient event). When FIFO buffer is enabled (MCSPI_CH(I)CONF[FFER] set to 1), the RX_full is asserted as soon as there is a number of bytes holds in buffer to read defined by MCSPI_XFERLEVEL[AFL].

Receiver register must be read to remove source of interrupt and RX_full interrupt status bit must be cleared for interrupt line de-assertion (if event enable as interrupt source).

When FIFO is enabled, no new RX_full event will be asserted as soon as Local Host has not performed the number of read into receive register defined by MCSPI_XFERLEVEL[AFL]. It is the responsibility of Local Host to perform the right number of reads.

23.3.4.2.4 RX_OVERFLOW

The RX0_OVERFLOW event is activated in slave mode in either transmit-and-receive or receive-only mode, when a channel is enabled and the SPI_RX*n* register or FIFO is full when a new SPI word is received. The SPI_RX*n* register is always overwritten with the new SPI word. If the FIFO is enabled data within the FIFO are overwritten, it must be considered as corrupted. The RX0_OVERFLOW event should not appear in slave mode using the FIFO.

The RX0_OVERFLOW indicates an error (data loss) in slave mode.

The SPI_IRQSTATUS[3] RX0_OVERFLOW interrupt status bit must be cleared for interrupt line deassertion (if the event is enabled as the interrupt source).

23.3.4.2.5 End of Word Count

The event EOW (End Of Word count) is activated when channel is enabled and configured to use the built-in FIFO. This interrupt is raised when the controller had performed the number of transfer defined in MCSPI_XFERLEVEL[WCNT] register. If the value was programmed to 0000h, the counter is not enabled and this interrupt is not generated.

The End of Word count interrupt also indicates that the SPI transfer is halt on channel using the FIFO buffer as soon as MCSPI_XFERLEVEL[WCNT] is not reloaded and channel re-enabled.

End of Word interrupt status bit must be cleared for interrupt line de-assertion (if event enable as interrupt source).

23.3.4.3 Slave Transmit-and-Receive Mode

The slave transmit and receive mode is programmable (bits TRM cleared to 0 in the register MCSPI_CH(I)CONF).

After the channel is enabled, transmission and reception proceed with interrupt and DMA request events.

In slave transmit and receive mode, transmitter register should be loaded before McSPI is selected by an external SPI master device.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Transmitter register or FIFO (if use of buffer enabled) content is always loaded in shift register whether it has been updated or not. The event TX_underflow is activated accordingly, and does not prevent transmission.

On completion of SPI word transfer (bit EOT of the register MCSPI_CH(I)STAT is set) the received data is transferred to the channel receive register. This bit is meaningless when using the Buffer for this channel.

The built-in FIFO is available in this mode and can be configured in one data direction Transmit or Receive, then the FIFO is seen as a unique FFNBYTE bytes buffer, or it can also be configured in both data direction Transmit and Receive, then the FIFO is split into two separate FFNBYTE/2 bytes buffer with their own address space management, in this last case the definition of AEL and AFL levels is based on FFNBYTE bytes and is under Local Host responsibility.

23.3.4.4 Slave Receive-Only Mode

The slave receive mode is programmable (bits TRM set to 01 in the register (I)CONF).

In receive only mode, the Transmitter register should be loaded before McSPI is selected by an external SPI master device. Transmitter register or FIFO (if use of buffer enabled) content is always loaded in shift register whether it has been updated or not. The event TX_underflow is activated accordingly, and does not prevent transmission.

When an SPI word transfer completes (the SPIm.SPI_CH*n*STAT0[2] EOT bit (with *n* = 0) is set to 1), the received data is transferred to the channel receive register.

To use McSPI as a slave receive only device with MCSPI_CH(I)CONF[TRM]=00, the user has the responsibility of the inhibition of the TX_empty and TX_underflow interrupts and DMA write requests due to the transmitter register sate.

On completion of SPI word transfer (bit EOT of the register MCSPI_CH(I)STAT is set) the received data is transferred to the channel receive register. This bit is meaningless when using the Buffer for this channel. The built-in FIFO is available in this mode and can be configured with FFER bit field in the MCSPI_CH(I)CONF register, then the FIFO is seen as a unique FFNBYTE bytes buffer.

Figure 23-24 shows an example of a half-duplex system with a master device on the left and a receive-only slave device on the right. Each time a bit transfers out from the master, 1 bit transfers in from the slave. After eight cycles of the serial clock spim_clk, Word A transfers from the master to the slave.

Figure 23-24. SPI Half-Duplex Transmission (Receive-Only Slave)

Copyright © 2011, Texas Instruments Incorporated

23.3.4.5 Slave Transmit-Only Mode

The slave transmit only mode is programmable (bits TRM set to 10 in the register MCSPI_CH(I)CONF). This mode avoids the CPU to read the receiver register (minimizing data movement) when only transmission is meaningful.

To use McSPI as a slave transmit only device with (I)CONF[TRM]=00, the user should inhibit the RX_full and RX_overflow interrupts and DMA read requests due to the receiver register sate.

On completion of SPI word transfer the bit EOT of the register MCSPI_CH(I)STAT is set. This bit is meaningless when using the Buffer for this channel.

The built-in FIFO is available in this mode and can be configured with FFER bit field in the MCSPI_CH(I)CONF register, then the FIFO is seen as a unique FFNBYTE bytes buffer.

Figure 23-25 shows a half-duplex system with a master device on the left and a transmit-only slave device on the right. Each time a bit transfers out from the slave device, 1 bit transfers in the master. After eight cycles of the serial clock spim_clk, WordB transfers from the slave to the master.

Figure 23-25. SPI Half-Duplex Transmission (Transmit-Only Slave)

23.3.5 Interrupts

According to its transmitter register state and its receiver register state each channel can issue interrupt events if they are enabled.

The interrupt events are listed in the Section 23.3.3.2 and in Section 23.3.4.2.

Each interrupt event has a status bit, in the MCSPI_IRQSTATUS register, which indicates service is required, and an interrupt enable bit, in the MCSPI_IRQENABLE register, which enables the status to generate hardware interrupt requests.

When an interrupt occurs and later a mask is applied on it (IRQENABLE), the interrupt line is not asserted again even if the interrupt source has not been serviced.

McSPI supports interrupt driven operation and polling.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

23.3.5.1 Interrupt-Driven Operation

Alternatively, an interrupt enable bit, in the MCSPI_IRQENABLE register, can be set to enable each of the events to generate interrupt requests when the corresponding event occurs. Status bits are automatically set by hardware logic conditions.

When an event occurs (the single interrupt line is asserted), the CPU must:

- Read the MCSPI_IRQSTATUS register to identify which event occurred,
- Read the receiver register that corresponds to the event, to remove the source of an RX_full event, or Write into the transmitter register that corresponds to the event, to remove the source of a TX_empty event. No action is needed to remove the source of the events TX_underflow and RX_overflow.
- Write a 1 into the corresponding bit of MCSPI_IRQSTATUS register to clear the interrupt status, and release the interrupt line.

The interrupt status bit should always be reset after channel enabling and before event are enabled as interrupt source.

23.3.5.2 Polling

When the interrupt capability of an event is disabled in the MCSPI_IRQENABLE register, the interrupt line is not asserted and:

- The status bits in the MCSPI_IRQSTATUS register can be polled by software to detect when the corresponding event occurs.
- Once the expected event occurs, CPU must: Read the receiver register that corresponds to the event, to remove the source of an RX_full event, or write into the transmitter register that corresponds to the event, to remove the source of a TX_empty event. No action is needed to remove the source of the events TX_underflow and RX_overflow.
- Writing a 1 into the corresponding bit of MCSPI_IRQSTATUS register clears the interrupt status and does not affect the interrupt line state.

23.3.6 DMA Requests

McSPI can be interfaced with a DMA controller. At system level, the advantage is to discharge the local host of the data transfers.

According to its transmitter register state, its receiver register state or FIFO level (if use of buffer for the channel) each channel can issue DMA requests if they are enabled.

The DMA requests need to be disabled in order to get TX and RX interrupts, in order to define either the end of the transfer or the transfer of the last words for the modes listed below:

- Master Transmit On
- Master normal receive only mode
- Master turbo receive only m
- Slave Transmit Only

There are 2 DMA request lines per channel. The management of DMA requests differ according to use of FIFO buffer or not:

23.3.6.1 FIFO Buffer Disabled

The DMA Read request line is asserted when the channel is enabled and a new data is available in the receive register of the channel. DMA Read request can be individually masked with the bit DMAR of the register MCSPI_CH(I)CONF. The DMA Read request line is de-asserted (OCP compliant as defined in [1]) on read completion of the receive register of the channel.

The DMA Write request line is asserted when the channel is enabled and the transmitter register of the channel is empty. DMA Write request can be individually masked with the bit DMAW of the register MCSPI_CH(I)CONF. The DMA Write request line is deasserted (OCP compliant as defined in [1]) on load completion of the transmitter register of the channel.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Only one SPI word can be transmitted/received per OCP bus access to write/read the transmit or receive register.

23.3.6.2 FIFO Buffer Enabled

The DMA Read request line is asserted when the channel is enabled and a number of bytes defined in MCSPI_XFERLEVEL[AFL] bit field is hold in FIFO buffer for the receive register of the channel. DMA Read request can be individually masked with the bit DMAR of the register MCSPI_CH(I)CONF. The DMA Read request line is de-asserted (OCP compliant as defined in [1]) on the first SPI word read completion of the receive register of the channel. No new DMA request will be asserted again as soon as user has not performed the right number of read accesses defined by MCSPI_XFERLEVEL[AFL] it is under user responsibility.

The DMA Write request line is asserted when the channel is enabled and the number of bytes hold in FIFO buffer is below the level defined by the MCSPI_XFERLEVEL[AEL] bit field. DMA Write request can be individually masked with the bit DMAW of the register MCSPI_CH(I)CONF. The DMA Write request line is de-asserted (OCP compliant as defined in [1]) on load completion of the first SPI word in the transmitter register of the channel. No new DMA request will be asserted again as soon as user has not performed the right number of write accesses defined by MCSPI_XFERLEVEL[AEL] it is under user responsibility.

Only one SPI word can be transmitted/received per OCP bus access to write/read the transmit or receive FIFO.

23.3.6.3 DMA 256 Bit Aligned Addresses

The controller has two registers MCSPI_DAFTX and MCSPI_DAFRX only used with an enabled channel which manages the FIFO to be compliant the a DMA handler providing only 256 bit aligned addresses.

This features is activated when the bit field MCSPI_MODULCTRL[8] FDAA is set to ‘1’ and only one enabled channel have its bit field MCSPI_CH(I)CONF[27] FFE(I)W or MCSPI_CH(I)CONF[28] FFE(I)R enabled.

In this case the registers MCSPI_TX(I) and MCSPI_RX(I) are not used and datas are managed through registers MCSPI_DAFTX and MCSPI_DAFRX.

23.3.7 Emulation Mode

The MReqDebug input differentiates a regular access of a processor (application access), from an emulator access.

Application access: MReqDebug = 0

In functional mode, the consequences of a read of a receiver register MCSPI_RX(i) are the following:

- The source of an RXi_Full event in the MCSPI_IRQSTATUS register is removed, if it was enabled in the MCSPI_IRQENABLE register.
- The RXiS status bit in the MCSPI_IRQSTATUS register is cleared.
- In master mode, depending on the round robin arbitration, and the transmitter register state, the channel may access to the shift register for transmission/reception.

Emulator access: MReqDebug = 1

In emulation mode, McSPI behavior is the same as in functional mode but a read of a receiver register MCSPI_RX(i) is not intrusive:

- MCSPI_RX(i) is still considered as not read. When the FIFO buffer is enabled, pointers are not updated.
- The source of an RXi_Full event in the MCSPI_IRQSTATUS register is not removed. The RXiS status bit in the MCSPI_CH(i)STAT register is held steady.

In emulation mode, as in functional mode, based on the ongoing data transfers, the status bits of the MCSPI_CH(i)STAT register may be optionally updated, the interrupt and DMA request lines may be optionally asserted.

23.3.8 Power Saving Management

Independently of the module operational modes (Transmit and/or Receive), two modes of operations are defined from a power management perspective: normal and idle modes.

The two modes are temporally fully exclusive.

McSPI is compliant with the profile “IdleReq / SIdleAck / Swakup” in the Idle mode defined in reference [4].

23.3.8.1 Normal Mode

Both the OCP clock and SPI clock (CLKSPIREF) provided to McSPI must be active for both master and slave modes. The auto-gating of the module OCP clock and SPI clock occurs when the following conditions are met:

- The bit AutoIdle of the register MCSPI_SYSCONFIG is set.
- In master mode, there is no data to transmit or receive in all channels.
- In slave mode, the SPI is not selected by the external SPI master device and no OCP accesses.

Autogating of the module OCP clock and SPI clock stops when the following conditions are met:

- In master mode, an OCP access occurs.
- In slave mode, an OCP access occurs or McSPI is selected by an external SPI master device.

23.3.8.2 Idle Mode

The OCP clock and SPI clock provided to McSPI may be switched off on system power manager request and switched back on module request.

McSPI is compliant with the power management handshaking protocol: idle request from the system power manager, idle acknowledgement from McSPI.

The idle acknowledgement in response to an idle request from the system power manager varies according to a programmable mode in the MCSPI_SYSCONFIG register: No idle mode, force idle mode, and smart idle mode.

- When programmed for no idle mode (the bit SIdleMode of the register MCSPI_SYSCONFIG is set to “01”), the module ignores the system power manager request, and behaves normally, as if the request was not asserted.
- When programmed for smart idle mode (the bit SIdleMode of the register MCSPI_SYSCONFIG is set to “10”), the module acknowledges the system power manager request according to its internal state.
- When programmed for force idle mode (the bit SIdleMode of the register MCSPI_SYSCONFIG is set to “00”), the module acknowledges the system power manager request unconditionally.

The OCP clock will be optionally switched off, during the smart idle mode period, if the bit ClockActivity of the register MCSPI_SYSCONFIG is set.

The SPI clock will be optionally switched off, during the smart idle mode period, if the second bit ClockActivity of the register MCSPI_SYSCONFIG is set.

McSPI assumes that both clocks may be switched off whatever the value set in the field ClockActivity of the register MCSPI_SYSCONFIG.

23.3.8.2.1 Transitions from Normal Mode to Smart-Idle Mode

The module detects an idle request when the synchronous signal IdleReq is asserted.

When IdleReq is asserted, any access to the module will generate an error as long as the OCP clock is alive.

When configured as a slave device, McSPI responds to the idle request by asserting the SIdleAck signal (idle acknowledgement) only after completion of the current transfer (SPIEN slave selection signal deasserted by the external master) and if interrupt or DMA request lines are not asserted.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

As a master device, McSPI responds to the idle request by asserting the SIdleAck signal (idle acknowledgement) only after completion of all the channel data transfers and if interrupt or DMA request lines are not asserted.

As long as SIdleAck is not asserted, if an event occurs, the module can still generate an interrupt or a DMA request after IdleReq assertion. In this case, the module ignores the idle request and SIdleAck will not get asserted: The system power manager will abort the power mode transition procedure. It is then the responsibility of the system to de-assert IdleReq before attempting to access the module.

When SIdleAck is asserted, the module does not assert any new interrupt or DMA request.

23.3.8.2.2 Transition From Smart-Idle Mode to Normal mode

McSPI detects the end of the idle period when the idle request signal (IdleReq) is deasserted.

Upon IdleReq de-assertion, the module switches back to normal mode and de-asserts SIdleAck signal. The module is fully operational.

23.3.8.2.3 Force-Idle Mode

Force-idle mode is enabled as follows:

- The bit SIdleMode of the register MCSPI_SYSCONFIG is cleared to “00” (Force Idle).

  The force idle mode is an idle mode where McSPI responds unconditionally to the idle request by asserting the SIdleAck signal and by deasserting unconditionally the interrupt and DMA request lines if asserted.

  The transition from normal mode to idle mode does not affect the interrupt event bits of the MCSPI_IRQSTATUS register.

  In force-idle mode, the module is supposed to be disabled at that time, so the interrupt and DMA request lines are likely deasserted. OCP clock and SPI clock provided to McSPI can be switched off.

  An idle request during an SPI data transfer can lead to an unexpected and unpredictable result, and is under software responsibility.

  Any access to the module in force idle mode will generate an error as long as the OCP clock is alive and IdleReq is asserted.

The module exits the force idle mode when:

- The idle request signal (IdleReq) is de-asserted.

  Upon IdleReq de-assertion, the module switches back to normal mode and de-asserts SIdleAck signal. The module is fully operational. The interrupt and DMA request lines are optionally asserted a clock cycle later.

23.3.9 System Test Mode

McSPI is in system test mode (SYSTEST) when the bit System_Test of the register MCSPI_MODULCTRL is set.

The SYSTEST mode is used to check in a very simple manner the correctness of the system interconnect either internally to interrupt handler, or power manager, or externally to SPI I/Os.

I/O verification can be performed in SYSTEST mode by toggling the outputs and capturing the logic state of the inputs. (See MCSPI_SYST register definition in Section 23.5.5)

23.3.10 Reset

23.3.10.1 Internal Reset Monitoring

The module is reset by the hardware when an active-low reset signal, synchronous to the OCP interface clock is asserted on the input pin RESETN.

This hardware reset signal has a global reset action on the module. All configuration registers and all state machines are reset, in all clock domains.

Copyright © 2011, Texas Instruments Incorporated

DRAFT ONLY

Additionally, the module can be reset by software through the bit SoftReset of the register MCSPI_SYSCONFIG. This bit has exactly the same action on the module logic as the hardware RESETN signal. The register MCSPI_SYSCONFIG is not sensitive to software reset. The SoftReset control bit is active high. The bit is automatically reset to 0 by the hardware.

A global ResetDone status bit is provided in the status register MCSPI_SYSSTATUS. This bit is set to 1 when all the different clock domains resets (OCP domain and SPI domains) have been released (logical AND).

The global ResetDone status bit can be monitored by the software to check if the module is ready-to-use following a reset (either hardware or software).

The clock CLKSPIREF must be provided to the module, in order to allow the ResetDone status bit to be set.

When used in slave mode, the clock CLKSPIREF is needed only during the reset phase. The clock CLKSPIREF can be switched off after the ResetDone status is set.

23.3.10.2 Reset values of registers

The reset values of registers and signals are described in Section 23.5.

23.3.11 Access to Data Registers

This section details the supported data accesses (read or write) from/to the data receiver registers MCSPI_RX(i) and data transmitter registers MCSPI_TX(i).

Supported access:

McSPI supports only one SPI word per register (receiver or transmitter) and does not support successive 8-bit or 16-bit accesses for a single SPI word.

The SPI word received is always right justified on LSbit of the 32bit register MCSPI_RX(i), and the SPI word to transmit is always right justified on LSbit of the 32bit register MCSPI_TX(i).

The upper bits, above SPI word length, are ignored and the content of the data registers is not reset between the SPI data transfers.

The coherence between the number of bits of the SPI Word, the number of bits of the access and the enabled byte remains under the user's responsibility. Only aligned accesses are supported.

In Master mode, data should not be written in the transmit register when the channel is disbaled.

23.3.12 Programming Aid

23.3.12.1 Module Initialization

- Hard or soft reset.
- Read MCSPI_SYSSTATUS.
- Check if reset is done.
- Module configuration: (a) Write into MCSPI_MODULCTRL (b) Write into MCSPI_SYSCONFIG.
- Before the ResetDone bit is set, the clocks CLK and CLKSPIREF must be provided to the module.
- To avoid hazardous behavior, it is advised to reset the module before changing from MASTER mode to SLAVE mode or from SLAVE mode to MASTER mode.

23.3.12.2 Common Transfer Sequence

McSPI module allows the transfer of one or several words, according to different modes:

- MASTER, MASTER Turbo, MASTER LoSSI, SLAVE
- TRANSMIT - RECEIVE, TRANSMIT ONLY, RECEIVE ONLY
- Write and Read requests: Interrupts, DMA
- SPIEN lines assertion/deassertion: automatic, manual

Copyright © 2011, Texas Instruments Incorporated

For all these flows, the host process contains the main process and the interrupt routines. The interrupt routines are called on the interrupt signals or by an internal call if the module is used in polling mode.

In multi-channel master mode, the flows of different channels can be run simultaneously.

23.3.12.3 Main Program

- Interrupt Initialization: (a) Reset status bits in MCSPI_IRQSTATUS (b) Enable interrupts in MCSPI_IRQENA.
- Channel Configuration: Write MCSPI_CH(i)CONF.
- Start the channel: Write 0000 0001h in MCSPI_CH(i)CTRL.
- First write request: TX empty - Generate DMA write event/ polling TX empty flag by CPU to write First transmit word into MCSPI_TX(i).
- End of transfer: Stop the channel by writing 0000 0000h in MCSPI_CH(i)CTRL

The end of transfer depends on the transfer mode.

In multi-channel master mode, be careful not to overwrite the bits of other channels when initializing MCSPI_IRQSTATUS and MCSPI_IRQENABLE.

23.3.13 Interrupt and DMA Events

McSPI has two DMA requests (Rx and Tx) per channel. It also has one interrupt line for all the interrupt requests.

23.4 Use Cases

23.5.1 McSPI System Configuration Register (MCSPI_SYSCONFIG)

The McSPI system configuration register (MCSPI_SYSCONFIG) allows control of various parameters of the module interface. It is not sensitive to software reset. The MCSPI_SYSCONFIG is shown in Figure 23-26 and described in Table 23-12.

Figure 23-26. McSPI System Configuration Register (MCSPI_SYSCONFIG)

23.5.2 McSPI System Status Register (MCSPI_SYSSTATUS)

The McSPI system status register (MCSPI_SYSSTATUS) provides status information about the module excluding the interrupt status information. The MCSPI_SYSSTATUS is shown in Figure 23-27 and described in Table 23-13.

Figure 23-27. McSPI System Status Register (MCSPI_SYSSTATUS)

23.5.3 McSPI Interrupt Status Register (MCSPI_IRQSTATUS)

The McSPI interrupt status register (MCSPI_IRQSTATUS) regroups all the status of the module internal events that can generate an interrupt. The MCSPI_IRQSTATUS is shown in Figure 23-28 and described in Table 23-14.

NOTE: In SYSTEST mode, the bits of this register have no meaning and always read 0.

Table 23-14. McSPI Interrupt Status Register (MCSPI_IRQSTATUS) Field Descriptions

Bit	Field	Value	Description
31-18	Reserved	0	Reads returns 0
17	EOW		End of word (EOW) count event when a channel is enabled using the FIFO buffer and the channel has sent the number of McSPI words defined by the MCSPI_XFERLEVEL[WCNT].
		Write 0	Event status bit is unchanged.
		Read 0	Event false.
		Write 1	Event status bit is reset.
		Read 1	Event is pending.
16	Reserved	0	Reserved
15	Reserved	0	Reads returns 0
14	RX3_FULL		Receiver register is full or almost full. Only when Channel 3 is enabled. This bit indicate FIFO almost full status when built-in FIFO is used for receive register (MCSPI_CH3CONF[FFE3R] is set).
		Write 0	Event status bit is unchanged.
		Read 0	Event false.
		Write 1	Event status bit is reset.
		Read 1	Event is pending.
13	TX3_UNDERFLOW		Transmitter register underflow. Only when Channel 3 is enabled. The transmitter register is empty (not updated by Host or DMA with new data) before its time slot assignment.
			Exception: No TX_underflow event when no data has been loaded into the transmitter register since channel has been enabled.
		Write 0	Event status bit is unchanged.
		Read 0	Event false.
		Write 1	Event status bit is reset.
		Read 1	Event is pending.

23.5.5 McSPI System Register (MCSPI_SYST)

This McSPI system register (MCSPI_SYST) is used to configure the system interconnect either internally to the peripheral bus or externally to the device I/O pads, when the module is configured in the system test (SYSTEST) mode. The MCSPI_SYST is shown in Figure 23-30 and described in Table 23-16.

Figure 23-30. McSPI System Register (MCSPI_SYST)

LEGEND: R/W = Read/Write; -*n* = value after reset

Table 23-16. McSPI System Register (MCSPI_SYST) Field Descriptions

Bit	Field	Value	Description
31-12	Reserved	0	Reads returns 0
11	SSB		Set status bit. This bit must be cleared prior attempting to clear a status bit of the MCSPI_IRQSTATUS register.
		0	No action. Writing 0 does not clear already set status bits.
			This bit must be cleared prior attempting to clear a status bit of the <MCSPI_IRQSTATUS> register.
		1	Writing 1 sets to 1 all status bits contained in the MCSPI_IRQSTATUS register.
			Writing 1 into this bit sets to 1 all status bits contained in the <MCSPI_IRQSTATUS> register.
10	SPIENDIR		Sets the direction of the SPIEN[3:0] lines and SPICLK line.
		0	Output (as in master mode).
		1	Input (as in slave mode).
9	SPIDATDIR1		Sets the direction of the SPIDAT[1].
		0	Output
		1	Input
8	SPIDATDIR0		Sets the direction of the SPIDAT[0].
		0	Output
		1	Input
7	Reserved	0	Reserved
6	SPICLK		SPICLK line (signal data value)
			If MCSPI_SYST[SPIENDIR] = 1 (input mode direction), this bit returns the value on the CLKSPI line (high or low), and a write into this bit has no effect.
			If MCSPI_SYST[SPIENDIR] = 0 (output mode direction), the CLKSPI line is driven high or low according to the value written into this register.
5	SPIDAT_1		SPIDAT[1] line (signal data value)
			If MCSPI_SYST[SPIDATDIR1] = 0 (output mode direction), the SPIDAT[1] line is driven high or low according to the value written into this register.
			If MCSPI_SYST[SPIDATDIR1] = 1 (input mode direction), this bit returns the value on the SPIDAT[1] line (high or low), and a write into this bit has no effect.
4	SPIDAT_0		SPIDAT[0] line (signal data value)
			If MCSPI_SYST[SPIDATDIR0] = 0 (output mode direction), the SPIDAT[0] line is driven high or low according to the value written into this register.
			If MCSPI_SYST[SPIDATDIR0] = 1 (input mode direction), this bit returns the value on the SPIDAT[0] line (high or low), and a write into this bit has no effect.

R/W-0															R/W-0

7	6			4	3	2	1	0
MOA	INITDLY				SYSTEM_TEST	MS	PIN34	SINGLE
R/W-0	R/W-0				R/W-0	R/W-0	R/W-0	R/W-0

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 23-17. McSPI Module Control Register(MCSPI_MODULCTRL) Field Descriptions

Bit	Field	Value	Description
31-9	Reserved	0	
8	FDAA		FIFO DMA Address 256-bit aligned. This register is used when a FIFO is managed by the module and DMA connected to the controller provides only 256 bit aligned address. If this bit is set the enabled channel which uses the FIFO has its datas managed through MCSPI_DAFTX and MCSPI_DAFRX registers instead of MCSPI_TX(i) and MCSPI_RX(i) registers.
		0	FIFO data managed by MCSPI_TX(i) and MCSPI_RX(i) registers.
		1	FIFO data managed by MCSPI_DAFTX and MCSPI_DAFRX registers.
7	MOA		Multiple word ocp access. This register can only be used when a channel is enabled using a FIFO. It allows the system to perform multiple SPI word access for a single 32-bit OCP word access. This is possible for WL < 16.
		0	Multiple word access disabled
		1	Multiple word access enabled with FIFO
6-4	INITDLY		Initial SPI delay for first transfer. This register is an option only available in SINGLE master mode, The controller waits for a delay to transmit the first SPI word after channel enabled and corresponding TX register filled. This Delay is based on SPI output frequency clock, No clock output provided to the boundary and chip select is not active in 4 pin mode within this period.
		0	No delay for first SPI transfer
		1h	The controller wait 4 SPI bus clock
		2h	The controller wait 8 SPI bus clock
		3h	The controller wait 16 SPI bus clock
		4h	The controller wait 32 SPI bus clock
		5h-Fh	Reserved
3	SYSTEM_TEST		Enables the system test mode
		0	Functional mode
		1	System test mode (SYSTEST)
2	MS		Master/ Slave
		0	Master - The module generates the SPICLK and SPIEN[3:0]
		1	Slave - The module receives the SPICLK and SPIEN[3:0]
1	PIN34		Pin mode selection. This register is used to configure the SPI pin mode, in master or slave mode. If asserted the controller only use SIMO,SOMI and SPICLK clock pin for SPI transfers.
		0	SPIEN is used as a chip select.
		1	SPIEN is not used.
			In this mode all related option to chip select have no meaning.

Table 23-18. McSPI Channel *(i)* Configuration Register (MCSPI_CH(i)CONF) Field Descriptions

Bit	Field	Value	Description
31-30	Reserved	0	Read returns 0
29	CLKG		Clock divider granularity. This register defines the granularity of channel clock divider: power of two or one clock cycle granularity. When this bit is set the register MCSPI_CHCTRL[EXTCLK] must be configured to reach a maximum of 4096 clock divider ratio. Then The clock divider ratio is a concatenation of MCSPI_CHCONF[CLKD] and MCSPI_CHCTRL[EXTCLK] values.
		0	Clock granularity of power of 2
		1	1 clock cycle granularity
28	FFER		FIFO enabled for receive. Only one channel can have this bit set.
		0	The buffer is not used to receive data.
		1	The buffer is used to receive data.
27	FFEW		FIFO enabled for transmit. Only one channel can have this bit set.
		0	The buffer is not used to transmit data.
		1	The buffer is used to transmit data.
26-25	TCS		Chip select time control. This 2-bits field defines the number of interface clock cycles between CS toggling and first or last edge of SPI clock.
		0	0.5 clock cycles
		1h	1.5 clock cycles
		2h	2.5 clock cycles
		3h	3.5 clock cycles
24	SBPOL		Start bit polarity.
		0	Start bit polarity is held to 0 during SPI transfer.
		1	Start bit polarity is held to 1 during SPI transfer.
23	SBE		Start bit enable for SPI transfer.
		0	Default SPI transfer length as specified by WL bit field.
		1	Start bit D/CX added before SPI transfer. Polarity is defined by MCSPI_CH(i)CONF[SBPOL].

Table 23-18. McSPI Channel *(i)* Configuration Register (MCSPI_CH(i)CONF) Field Descriptions (continued)

Bit	Field	Value	Description
22-21	SPIENSLV		Channel 0 only and slave mode only: SPI slave select signal detection. Reserved bits (read returns 0) for other cases.
		0	Detection enabled only on SPIEN[0]
		1h	Detection enabled only on SPIEN[1]
		2h	Detection enabled only on SPIEN[2]
		3h	Detection enabled only on SPIEN[3]
20	FORCE		Manual SPIEN assertion to keep SPIEN active between SPI words. (single channel master mode only)
		0	Writing 0 into this bit drives the SPIEN line when MCSPI_CHCONF(i)[EPOL]=0, and drives it high when MCSPI_CHCONF(i)[EPOL]=1.
		1	Writing 1 into this bit drives the SPIEN line when MCSPI_CHCONF(i)[EPOL]=0, and drives it low when MCSPI_CHCONF(i)[EPOL]=1
19	TURBO		Turbo mode.
		0	Turbo is deactivated (recommended for single SPI word transfer).
		1	Turbo is activated to maximize the throughput for multi-SPI word transfers.
18	IS		Input select
		0	Data line 0 (SPIDAT[0]) selected for reception.
		1	Data line 1 (SPIDAT[1]) selected for reception.
17	DPE1		Transmission enable for data line 1 (SPIDATAGZEN[1])
		0	Data line 1 (SPIDAT[1]) selected for transmission
		1	No transmission on data line 1 (SPIDAT[1])
16	DPE0		Transmission enable for data line 0 (SPIDATAGZEN[0])
		0	Data line 0 (SPIDAT[0]) selected for transmission
		1	No transmission on data line 0 (SPIDAT[0])
15	DMAR		DMA read request. The DMA read request line is asserted when the channel is enabled and new data is available in the receive register of the channel. The DMA read request line is deasserted on read completion of the receive register of the channel.
		0	DMA read request is disabled.
		1	DMA read request is enabled.
14	DMAW		DMA write request. The DMA write request line is asserted when the channel is enabled and the MCSPI_TX*n* register of the channel is empty. The DMA write request line is deasserted on load completion of the MCSPI_TX*n* register of the channel.
		0	DMA write request is disabled.
		1	DMA write request is enabled.
13-12	TRM		Transmit/receive modes.
		0	Transmit and receive mode
		1h	Receive-only mode
		2h	Transmit-only mode
		3h	Reserved

23.5.8 McSPI Channel (*i*) Status Register (MCSPI_CH(i)STAT)

The McSPI channel *i* status register register (MCSPI_CH(i)STAT) provides status information about the McSPI channel *i* FIFO transmit buffer register (MCSPI_TX*n*) and the McSPI channel *i* FIFO receive buffer register (MCSPI_RX*n*) of channel *i*. The (MCSPI_CH(i)STAT) is shown in Figure 23-33 and described in Table 23-20.

Figure 23-33. McSPI Channel *(i)* Status Register (MCSPI_CH(i)STAT)

31							8
Reserved

R-0	R-0	R-0	R-0	R-0	R-0	R-0	R-0

LEGEND: R = Read only; -*n* = value after reset

Table 23-20. McSPI Channel *(i)* Status Register (MCSPI_CH(i)STAT) Field Descriptions

Bit	Field	Value	Description
31-7	Reserved	0	Read returns 0
6	RXFFF		Channel *i* FIFO receive buffer full status.
		0	FIFO receive buffer is not full.
		1	FIFO receive buffer is full.
5	RXFFE		Channel *i* FIFO receive buffer empty status.
		0	FIFO receive buffer is not empty.
		1	FIFO receive buffer is empty.
4	TXFFF		Channel *i* FIFO transmit buffer full status.
		0	FIFO transmit buffer is not full.
		1	FIFO transmit buffer is full.
3	TXFFE		Channel *i* FIFO transmit buffer empty status.
		0	FIFO transmit buffer is not empty.
		1	FIFO transmit buffer is empty.
2	EOT		Channel *i* end-of-transfer status. The definitions of beginning and end of transfer vary with master versus slave and the transfer format (transmit/receive mode, turbo mode).
		0	This flag is automatically cleared when the shift register is loaded with the data from the transmitter register (beginning of transfer).
		1	This flag is automatically set to one at the end of an SPI transfer.
1	TXS		Channel *i* transmitter register status. The bit is cleared when the host writes the most significant byte of the SPI word in the MCSPI_TX(i) register. The bit is set when enabling the channel *i* , and also when the SPI word is transferred from the MCSPI_TX(i) register to the shift register.
		0	Register is full.
		1	Register is empty.
0	RXS		Channel *i* receiver register status. The bit is cleared when enabling the channel *i*, and also when the host reads the most significant byte of the received SPI word from the MCSPI_RX(i) register. The bit is set when the received SPI word is transferred from the shift register to the MCSPI_RX(i) register.
		0	Register is empty.
		1	Register is full.

24.1 Introduction

24.1.1 Purpose of the Peripheral

The general-purpose interface combines four general-purpose input/output (GPIO) modules. Each GPIO module provides 32 dedicated general-purpose pins with input and output capabilities; thus, the general-purpose interface supports up to 128 (4 × 32) pins. These pins can be configured for the following applications:

- Data input (capture)/output (drive)
- Keyboard interface with a debounce cell
- Interrupt generation in active mode upon the detection of external events. Detected events are processed by two parallel independent interrupt-generation submodules to support biprocessor operations.
- Wake-up request generation in idle mode upon the detection of external events.

24.1.2 GPIO Features

Each GPIO module is made up of 32 identical channels. Each channel can be configured to be used in the following applications:

- Data input/output
- Keyboard interface with a de-bouncing cell
- Synchronous interrupt generation (in active mode) upon the detection of external events (signal transition(s) and/or signal level(s))
- Wake-up request generation (in Idle mode) upon the detection of signal transition(s)

Global features of the GPIO interface are:

- Synchronous interrupt requests from each channel are processed by two identical interrupt generation sub-modules to be used independently by the Host ARM, Ducati, and the GEM
- Wake-up requests from input channels are merged together to issue one wake-up signal to the system
- Shared registers can be accessed through “Set & Clear” protocol

24.1.3 Unsupported GPIO Features

The wake-up feature of the GPIO modules is only supported on GPIO0.

24.2 Integration

The device instantiates four GPIO_V2 modules. Each GPIO module provides the support for 32 dedicated pins with input and output configuration capabilities. Input signals can be used to generate interruptions and wake-up signal. Two Interrupt lines are available for bi-processor operation. Pins can be dedicated to be used as a keyboard controller.

With four GPIO modules, the device allows for a maximum of 128 GPIO pins. (The exact number available varies as a function of the device configuration and pin muxing.) GPIO0 is in the Wakeup domain and may be used to wakeup the device via external sources. GPIO[1:3] are located in the peripheral domain.

Figure 24-1 and Figure 24-2 show the GPIO integration.

24.2.1 GPIO Connectivity Attributes

The general connectivity attributes for the GPIO modules in the device are shown in Table 24-1 and Table 24-2.

Table 24-1. GPIO0 Connectivity Attributes

Attributes	Type
Power Domain	Wakeup Domain
Clock Domain	PD_WKUP_L4_WKUP_GCLK (OCP) GPIO_0_GDBCLK (Debounce)
Reset Signals	WKUP_DOM_RST_N
Idle/Wakeup Signals	Smart Idle / Slave Wakeup
Interrupt Requests	Two Interrupts: INTRPEND1 to MPU subsystem, PRUSS and WakeM3 INTRPEND2 to MPU subsystem and WakeM3
DMA Requests	None
Physical Address	L4 Wakeup slave port

Table 24-2. GPIO[1:3] Connectivity Attributes

Attributes	Type
Power Domain	Peripheral Domain
Clock Domain	PD_PER_L4LS_GCLK (OCP) GPIO_1_GDBCLK (GPIO1 Debounce) GPIO_2_GDBCLK (GPIO2 Debounce) GPIO_3_GDBCLK (GPIO3 Debounce)
Reset Signals	PER_DOM_RST_N
Idle/Wakeup Signals	Smart Idle
Interrupt Requests	Two Interrupts: INTRPEND1 to MPU subsystem INTRPEND2 to MPU subsystem
DMA Requests	None
Physical Address	L4 Peripheral slave port

24.2.2 GPIO Clock and Reset Management

The GPIO modules require two clocks: The de-bounce clock is used for the de-bouncing cells. The interface clock provided by the peripheral bus (L4 interface) is also the functional clock and is used through the entire GPIO module (except within the de-bouncing sub-module). It clocks the OCP interface and the internal logic. For GPIO0 the debounce clock is selected from one of three sources using the CLKSEL_GPIO0_DBCLK register in the PRCM:

- The on-chip ~32.768 KHz oscillator (CLK_RC32K)
- The PER PLL generated 32.768 KHz clock (CLK_32KHZ)
- The external 32.768 KHz oscillator/clock (CLK_32K_RTC)

24.3 Functional Description

This section discusses the operational details and basic functions of the GPIO peripheral.

24.3.1 Operating Modes

Four operating modes are defined for the module:

- **Active mode:** the module is running synchronously on the interface clock, interrupt can be generated according to the configuration and the external signals.
- **Idle mode:** the module is in a waiting state, interface clock can be stopped , no interrupt can be generated, a wake-up signal can be generated according to the configuration and external signals. Check the chip top-level functional specification for the availability of the debouncing clock while in Idle mode. If the debouncing clock is active, the debouncing cell can be used to sample and to filter the input to generate a wakeup event. Otherwise (debouncing clock inactive), the debouncing cell cannot be used, as it would gate all input signals.
- **Inactive mode:** the module has no activity, interface clock can be stopped, no interrupt can be generated, and the wake-up feature is inhibited.
- **Disabled mode:** the module is not used, internal clock paths are gated, no interrupt or wake-up request can be generated.

The Idle and Inactive modes are configured within the module and activated on request by the host processor through system interface sideband signals. The Disabled mode is set by software through a dedicated configuration bit. It unconditionally gates the internal clock paths not use for the system interface. All module registers are 8, 16 or 32-bit accessible through the OCP compatible interface (little endian encoding). In active mode, the event detection (level or transition) is performed in the GPIO module using the interface clock. The detection's precision is set by the frequency of this clock and the selected internal gating scheme.

24.3.2 Clocking and Reset Strategy

24.3.2.1 Clocks

GPIO module runs using two clocks:

- The debouncing clock is used for the debouncing sub-module logic (without the corresponding configuration registers). This module can sample the input line and filters the input level using a programmed delay.
- The interface clock provided by the peripheral bus (OCP compatible system interface). It is used through the entire GPIO module (except within the debouncing sub-module logic). It clocks the OCP interface and the internal logic. Clock gating features allow adapting the module power consumption to the activity.

24.3.2.2 Clocks, Gating and Active Edge Definitions

The interface clock provided by the peripheral bus (OCP compatible system interface) is used through the entire GPIO module. Two clock domains are defined: the OCP interface and the internal logic. Each clock domain can be controlled independently. Sampling operations for the data capture and for the events detection are done using the rising edge. The data loaded in the data output register (GPIO_DATAOUT) is set at the output GPIO pins synchronously with the rising edge of the interface clock.

Five clock gating features are available:

- Clock for the system interface logic can be gated when the module is not accessed, if the AUTOIDLE configuration bit in the system configuration register (GPIO_SYSCONFIG) is set. Otherwise, this logic is free running on the interface clock.
- Clock for the input data sample logic can be gated when the data in register is not accessed.
- Four clock groups are used for the logic in the synchronous events detection. Each 8 input GPIO_V2 pins group will have a separate enable signal depending on the edge/level detection register setting. If a group requires no detection, then the corresponding clock will be gated. All channels are also gated using a 'one out of N' scheme. N can take the values 1, 2, 4 or 8. The interface clock is enabled for

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

this logic one cycle every N cycles. When N is equal to 1, there is no gating and this logic is free running on the interface clock. When N is between 2 to 8, this logic is running at the equivalent frequency of interface clock frequency divided by N.

- In Inactive mode, all internal clock paths are gated.
- In Disabled mode, all internal clock paths not used for the system interface are gated. All GPIO registers are accessible synchronously with the interface clock.

24.3.2.3 Sleep Mode Request and Acknowledge

Upon a Sleep mode request issued by the host processor, the GPIO module goes to the Idle mode according to the IDLEMODE field in the system configuration register (GPIO_SYSCONFIG).

- IDLEMODE = 0 (Force-Idle mode): the GPIO goes in Inactive mode independently of the internal module state and the Idle acknowledge is unconditionally sent. In Force-Idle mode, the module is in Inactive mode and its wake-up feature is totally inhibited.
- IDLEMODE = 1h (No-Idle mode): the GPIO does not go to the Idle mode and the Idle acknowledge is never sent.
- IDLEMODE = 2h (Smart-Idle mode) or IDLEMODE = 3h (Smart-Idle mode): the GPIO module evaluates its internal capability to have the interface clock switched off. Once there is no more internal activity (the data input register completed to capture the input GPIO pins, there is no pending interrupt, all interrupt status bits are cleared, and there is no write access to GPIO_DEBOUNCINGTIME register pending to be synchronized), the Idle acknowledge is asserted and the GPIO enters Idle mode, ready to issue a wake-up request when the expected transition occurs on an enabled GPIO input pin. This wake-up request is effectively sent only if the ENAWAKEUP bit in GPIO_SYSCONFIG is set to enable the GPIO wakeup capability. When the system is awake, the Idle Request goes inactive, the Idle acknowledge and wake-up request (if it is the GPIO that triggered the system's wakeup) signals are immediately de-asserted, and the asynchronous wake-up request (if existing) is reflected into the synchronous interrupt status registers.

NOTE: Idle mode request and Idle acknowledge are system interface sideband signals. Once the GPIO acknowledges the Sleep mode request (Idle acknowledge has been sent), the interface clock can be stopped anytime.

Upon a Sleep mode request issued by the host processor, the GPIO module goes to the Idle mode only if there is no active bit in GPIO_IRQSTATUS_RAW_n registers.

24.3.2.4 Reset

The OCP hardware Reset signal has a global reset action on the GPIO. All configuration registers, all DFFs clocked with the Interface clock or Debouncing clock and all internal state machines are reset when the OCP hardware Reset is active (low level). The RESETDONE bit in the system status register (GPIO_SYSSTATUS) monitors the internal reset status: it is set when the Reset is completed on both OCP and Debouncing clock domains. The software Reset (SOFTRESET bit in the system configuration register) has the same effect as the OCP hardware Reset signal, and the RESETDONE bit in GPIO_SYSSTATUS is updated in the same condition.

24.3.3 Interrupt and Wake-up Features

24.3.3.1 Functional Description

In order to generate an interrupt request to a host processor upon a defined event (level or logic transition) occurring on a GPIO pin, the GPIO configuration registers have to be programmed as follows:

- Interrupts for the GPIO channel must be enabled in the GPIO_IRQSTATUS_SET_0 and/or GPIO_IRQSTATUS_SET_1 registers.
- The expected event(s) on input GPIO to trigger the interrupt request has to be selected in the GPIO_LEVELDETECT0, GPIO_LEVELDETECT1, GPIO_RISINGDETECT, and GPIO_FALLINGDETECT registers.

Copyright © 2011, Texas Instruments Incorporated

In order to generate a wake-up request to a host processor upon a defined event (logic transition) occurring on a GPIO pin, the GPIO configuration registers have to be programmed as follows:

- The GPIO channel must be enabled in the GPIO_IRQWAKEN register.
- The expected event(s) on input GPIO to trigger the interrupt (or the wake-up) request has to be selected in the GPIO_RISINGDETECT and GPIO_FALLINGDETECT registers. Wake-up request can only be generated on rising and/or on falling transitions.

For instance, interrupt generation on both edges on input k is configured by setting to 1 the *k*th bit in registers GPIO_RISINGDETECT and GPIO_FALLINGDETECT along with the interrupt enabling for one or both interrupt lines (GPIO_IRQSTATUS_SET_n).

NOTE: All interrupt (or wake-up) sources (the 32 input GPIO channels) are merged together to issue two synchronous interrupt requests 1 and 2, and two asynchronous wake-up requests.

24.3.3.2 Synchronous Path: Interrupt Request Generation

In Active mode, once the GPIO configuration registers have been set to enable the interrupt generation, a synchronous path (Figure 24-3) samples the transitions and levels on the input GPIO with the internally gated interface clock. When an event matches the programmed settings, the corresponding bit in the GPIO_IRQSTATUS_RAW_n registers is set to 1 and, on the following interface clock cycle, the interrupt lines 1 and/or 2 are activated (depending on the GPIO_IRQSTATUS_SET_n registers).

Due to the sampling operation, the minimum pulse width on the input GPIO to trigger a synchronous interrupt request is two times the internally gated interface clock period (the internally gated interface clock period is equal to N times the interface clock period). This minimum pulse width has to be met before and after any expected level transition detection. Level detection requires the selected level to be stable for at least two times the internally gated interface clock period to trigger a synchronous interrupt.

As the module is synchronous, latency is minimal between the expected event occurrence and the activation of the interrupt line(s). This should not exceed 3 internally gated interface clock cycles + 2 interface clock cycles when the debouncing feature is not used. When the debouncing feature is active, the latency depends on the GPIO_DEBOUNCINGTIME register value and should be less than 3 internally gated interface clock cycles + 2 interface clock cycles + GPIO_DEBOUNCINGTIME value debouncing clock cycles + 3 debouncing clock cycles.

Figure 24-3. Interrupt Request Generation

24.3.3.3 Asynchronous Path: Wake-up Request Generation

In Idle mode (interface clock is shut down, the GPIO configuration registers have been previously programmed), an asynchronous path (Figure 24-4) detects the expected transition(s) on input GPIO (according to the registers programming) and activates an asynchronous wake-up request if the wakeup enable register is set. As shown in , there is only one external wake-up line, since all wake-up sources are merged together. Once the system is in wake up, the interface clock is re-started and, according to the input GPIO pin that triggered the wake-up request, the corresponding bits in the GPIO_IRQSTATUS_RAW_n registers are synchronously set to 1; on the following internal clock cycle, the interrupt lines 1 and/or 2 are active (active high) when the corresponding bits in GPIO_IRQSTATUS_SET_n registers are set.

NOTE: If debouncing is not enabled, there is no minimum input pulse width to trigger the wake-up request since there is no sampling operation.

If debouncing is used, the minimum pulse width is set by the debouncing specified time.

The ENAWAKEUP bit in the system configuration register (GPIO_SYSCONFIG) enables or disables the GPIO wake-up feature globally: if this bit is 0, the GPIO_IRQWAKEN has no effect.

Figure 24-4. Wake-Up Request Generation

Copyright © 2011, Texas Instruments Incorporated

24.3.3.4 Interrupt (or Wake-up) Line Release

When the host processor receives an interrupt request issued by the GPIO module, it can read the corresponding GPIO_IRQSTATUS_n register to find out which input GPIO has triggered the interrupt (or the wake-up request). After servicing the interrupt (or acknowledging the wake-up request), the processor resets the status bit and releases the interrupt line by writing a 1 in the corresponding bit of the GPIO_IRQSTATUS_n register. If there is still a pending interrupt request to serve (all bits in the GPIO_IRQSTATUS_RAW_n register not masked by the GPIO_IRQSTATUS_SET_n, which are not cleared by setting the GPIO_IRQSTATUS_CLR_n), the interrupt line will be re-asserted.

24.3.4 General-Purpose Interface Basic Programming Model

24.3.4.1 Power Saving by Grouping the Edge/Level Detection

Each GPIO module implements four gated clocks used by the edge/level detection logic to save power. Each group of eight input GPIO pins generates a separate enable signal depending on the edge/level detection register setting (because the input is 32 bits, four groups of eight inputs are defined for each GPIO module). If a group requires no edge/level detection, then the corresponding clock is gated (cut off). Grouping the edge/level enable can save the power consumption of the module as described in the following example.

If any of the registers:

- GPIO_LEVELDETECT0
- GPIO_LEVELDETECT1
- GPIO_RISINGDETECT
- GPIO_FALLINGDETECT

are set to 0101 0101h, then all clocks are active (power consumption is high);

are set to 0000 00FFh, then a single clock is active.

NOTE: When the clocks are enabled by writing to the GPIO_LEVELDETECT0, GPIO_LEVELDETECT1, GPIO_RISINGDETECT, and GPIO_FALLINGDETECT registers, the detection starts after 5 clock cycles. This period is required to clean the synchronization edge/level detection pipeline.

The mechanism is independent of each clock group. If the clock has been started before a new setting is performed, the following is recommended: first, set the new detection required; second, disable the previous setting (if necessary). In this way, the corresponding clock is not gated and the detection starts immediately.

24.3.4.2 Set and Clear Instructions

The GPIO module implements the set-and-clear protocol register update for the data output and interrupt enable, and wake-up enable registers. This protocol is an alternative to the atomic test and set operations and consists of writing operations at dedicated addresses (one address for setting bit[s] and one address for clearing bit[s]). The data to write is 1 at bit position(s) to clear (or to set) and 0 at unaffected bit(s).

Registers can be accessed in two ways:

- Standard: Full register read and write operations at the primary register address
- Set and clear (recommended): Separate addresses are provided to set (and clear) bits in registers. Writing 1 at these addresses sets (or clears) the corresponding bit into the equivalent register; writing a 0 has no effect.

Therefore, for these registers, three addresses are defined for one unique physical register. Reading these addresses has the same effect and returns the register value.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

24.3.4.2.1 Clear Instruction

24.3.4.2.1.1 Clear Interrupt Enable Registers (GPIO_IRQSTATUS_CLR_0 and GPIO_IRQSTATUS_CLR_1):

- A write operation in the clear interrupt enable1 (or enable2) register clears the corresponding bit in the interrupt enable1 (or enable2) register when the written bit is 1; a written bit at 0 has no effect.
- A read of the clear interrupt enable1 (or enable2) register returns the value of the interrupt enable1 (or enable2) register.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

24.3.4.2.1.2 Clear Wake-up Enable Register (GPIO_CLEARWKUENA):

- A write operation in the clear wake-up enable register clears the corresponding bit in the wake-up enable register when the written bit is 1; a written bit at 0 has no effect.
- A read of the clear wake-up enable register returns the value of the wake-up enable register.

24.3.4.2.1.3 Clear Data Output Register (GPIO_CLEARDATAOUT):

- A write operation in the clear data output register clears the corresponding bit in the data output register when the written bit is 1; a written bit at 0 has no effect.
- A read of the clear data output register returns the value of the data output register.

24.3.4.2.1.4 Clear Instruction Example

Assume the data output register (or one of the interrupt/wake-up enable registers) contains the binary value, 0000 0001 0000 0001h, and you want to clear bit 0.

With the clear instruction feature, write 0000 0000 0000 0001h at the address of the clear data output register (or at the address of the clear interrupt/wake-up enable register). After this write operation, a reading of the data output register (or the interrupt/wake-up enable register) returns 0000 0001 0000 0000h; bit 0 is cleared.

NOTE: Although the general-purpose interface registers are 32-bits wide, only the 16 least-significant bits are represented in this example.

Figure 24-5. Write @ GPIO_CLEARDATAOUT Register Example

24.3.4.2.2 Set Instruction

24.3.4.2.2.1 Set Interrupt Enable Registers (GPIO_IRQSTATUS_SET_0 and GPIO_IRQSTATUS_SET_1):

- A write operation in the set interrupt enable1 (or enable2) register sets the corresponding bit in the interrupt enable1 (or enable2) register when the written bit is 1; a written bit at 0 has no effect.
- A read of the set interrupt enable1 (or enable2) register returns the value of the interrupt enable1 (or enable2) register.

24.3.4.2.2.2 Set Wake-up Enable Register (GPIO_SETWKUENA):

- A write operation in the set wake-up enable register sets the corresponding bit in the wake-up enable register when the written bit is 1; a written bit at 0 has no effect.
- A read of the set wake-up enable register returns the value of the wake-up enable register.

24.3.4.2.2.3 Set Data Output Register (GPIO_SETDATAOUT):

- A write operation in the set data output register sets the corresponding bit in the data output register when the written bit is 1; a written bit at 0 has no effect.
- A read of the set data output register returns the value of the data output register.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

24.3.4.2.2.4 Set Instruction Example

Assume the interrupt enable1 (or enable2) register (or the data output register) contains the binary value, 0000 0001 0000 0000h, and you want to set bits 15, 3, 2, and 1.

With the set instruction feature, write 1000 0000 0000 1110h at the address of the set interrupt enable1 (or enable2) register (or at the address of the set data output register). After this write operation, a reading of the interrupt enable1 (or enable2) register (or the data output register) returns 1000 0001 0000 1110h; bits 15, 3, 2, and 1 are set.

NOTE: Although the general-purpose interface registers are 32-bits wide, only the 16 least-significant bits are represented in this example.

Figure 24-6. Write @ GPIO_SETIRQENABLEx Register Example

24.3.4.3 Data Input (Capture)/Output (Drive)

The output enable register (GPIO_OE) controls the output/input capability for each pin. At reset, all the GPIO-related pins are configured as input and output capabilities are disabled. This register is not used within the module; its only function is to carry the pads configuration.

When configured as an output (the desired bit reset in GPIO_OE), the value of the corresponding bit in the GPIO_DATAOUT register is driven on the corresponding GPIO pin. Data is written to the data output register synchronously with the interface clock. This register can be accessed with read/write operations or by using the alternate set and clear protocol register update feature. This feature lets you set or clear specific bits of this register with a single write access to the set data output register (GPIO_SETDATAOUT) or to the clear data output register (GPIO_CLEARDATAOUT) address. If the application uses a pin as an output and does not want interrupt/wake-up generation from this pin, the application must properly configure the wake-up enable and the interrupt enable registers.

When configured as an input (the desired bit set to 1 in GPIO_OE), the state of the input can be read from the corresponding bit in the GPIO_DATAIN register. The input data is sampled synchronously with the interface clock and then captured in the data input register synchronously with the interface clock. When the GPIO pin levels change, they are captured into this register after two interface clock cycles (the required cycles to synchronize and to write data). If the application uses a pin as an input, the application must properly configure the wake-up enable and the interrupt enable registers to the interrupt and wake-up feature as needed.

24.3.4.4 Debouncing Time

To enable the debounce feature for a pin, the GPIO configuration registers must be programmed as follows:

- The GPIO pin must be configured as input in the output enable register (write 1 to the corresponding bit of the GPIO_OE register).
- The debouncing time must be set in the debouncing value register (GPIO_DEBOUNCINGTIME). The GPIO_DEBOUNCINGTIME register is used to set the debouncing time for all input lines in the GPIO module. The value is global for all the ports of one GPIO module, so up to six different debouncing values are possible. The debounce cell is running with the debounce clock (32 kHz). This register represents the number of the clock cycle(s) (one cycle is 31 microseconds long) to be used.

  The following formula describes the required input stable time to be propagated to the debounced output:

Copyright © 2011, Texas Instruments Incorporated

Debouncing time = (DEBOUNCETIME + 1) × 31 µs

Where the DEBOUNCETIME field value in the GPIO_DEBOUNCINGTIME register is from 0 to 255.

- The debouncing feature must be enabled in the debouncing enable register (write 1 to the corresponding DEBOUNCEENABLE bit in the GPIO_DEBOUNCENABLE register).

24.3.4.5 GPIO as a Keyboard Interface

The general-purpose interface can be used as a keyboard interface (Figure 24-7). You can dedicate channels based on the keyboard matrix = * c). Figure 24-7 shows row channels configured as inputs with the input debounce feature enabled. The row channels are driven high with an external pull-up. Column channels are configured as outputs and drive a low level.

When a keyboard matrix key is pressed, the corresponding row and column lines are shorted together and a low level is driven on the corresponding row channel. This generates an interrupt based on the proper configuration (see Section 24.3.3).

When the keyboard interrupt is received, the processor can disable the keyboard interrupt and scan the column channels for the key coordinates.

- The scanning sequence has as many states as column channels: For each step in the sequence, the processor drives one column channel low and the others high.
- The processor reads the values of the row channels and thus detects which keys in the column are pressed.

At the end of the scanning sequence, the processor establishes which keys are pressed. The keyboard interface can then be reconfigured in the interrupt waiting state.

Figure 24-7. General-Purpose Interface Used as a Keyboard Interface

24.4 GPIO Registers

All module registers are 8-, 16-, or 32-bit accessible through the L4 interconnect (little-endian encoding). Access to registers is direct; no shadow registers are implemented.

24.4.1 GPIO_REVISION Register

The GPIO revision register is a read only register containing the revision number of the GPIO module. A write to this register has no effect, the same as the reset. The GPIO_REVISION register is shown in Figure 24-8 and described in Table 24-6.

Figure 24-8. GPIO_REVISION Register

31–30	29–28	27–16
SCHEME	Reserved	FUNC
R-1	R-1	R-60h

15–11	10–8	7–6	5–0
RTL	MAJOR	CUSTOM	MINOR
R-1	R-0	R-0	R-1

LEGEND: R/W = Read/Write; R = Read only; -*n* = value after reset

Table 24-6. GPIO_REVISION Register Field Descriptions

Bit	Field	Value	Description
31-30	SCHEME	1	Used to distinguish between old Scheme and current.
29-28	Reserved	1	Reserved
27-16	FUNC	0-FFFh	Indicates a software compatible module family.
15-11	RTL	0-1Fh	RTL version
10-8	MAJOR	0-7h	Major Revision
7-6	CUSTOM	0-3h	Indicates a special version for a particular device.
5-0	MINOR	0-3Fh	Minor Revision

24.4.2 GPIO_SYSCONFIG Register

The GPIO_SYSCONFIG register controls the various parameters of the L4 interconnect. The GPIO_SYSCONFIG register is shown in Figure 24-9 and described in Table 24-7.

NOTE: When the AUTOIDLE bit is set, the GPIO_DATAIN read command has a 3 OCP cycle latency due to the data in sample gating mechanism. When the AUTOIDLE bit is not set, the GPIO_DATAIN read command has a 2 OCP cycle latency.

Figure 24-9. GPIO_SYSCONFIG Register

24.4.4 GPIO_IRQSTATUS_RAW_n Register

The GPIO_IRQSTATUS_RAW_n register provides core status information for the interrupt handling, showing all active events (enabled and not enabled). The fields are read-write. Writing a 1 to a bit sets it to 1, that is, triggers the IRQ (mostly for debug). Writing a 0 has no effect, that is, the register value is not be modified. Only enabled, active events trigger an actual interrupt request on the IRQ output line. The GPIO_IRQSTATUS_RAW_n register is shown in Figure 24-11 and described in Table 24-9.

		0	No effect
		1	IRQ is triggered.

24.4.5 GPIO_IRQSTATUS_n Register

The GPIO_IRQSTATUS_n register provides core status information for the interrupt handling, showing all active events (enabled and not enabled). The fields are read-write. Writing a 1 to a bit clears the bit to 0, that is, clears the IRQ. Writing a 0 has no effect, that is, the register value is not modified. Only enabled, active events trigger an actual interrupt request on the IRQ output line. The GPIO_IRQSTATUS_n register is shown in Figure 24-12 and described in Table 24-10.

24.4.6 GPIO_IRQSTATUS_SET_n Register

All 1-bit fields in the GPIO_IRQSTATUS_SET_n register enable a specific interrupt event to trigger an interrupt request. Writing a 1 to a bit enables the interrupt field. Writing a 0 has no effect, that is, the register value is not modified. The GPIO_IRQSTATUS_SET_n register is shown in Figure 24-13 and described in Table 24-11.

		0	No effect
		1	Enable IRQ generation.

24.4.7 GPIO_IRQSTATUS_CLR_n Register

All 1-bit fields in the GPIO_IRQSTATUS_CLR_n register clear a specific interrupt event. Writing a 1 to a bit disables the interrupt field. Writing a 0 has no effect, that is, the register value is not modified. The GPIO_IRQSTATUS_CLR_n register is shown in Figure 24-14 and described in Table 24-12.

24.4.8 GPIO_IRQWAKEN_n Register

All 1-bit fields in the GPIO_IRQWAKEN_n register enable a specific (synchronous) IRQ request source to generate an asynchronous wakeup (on the appropriate wakeup line). The GPIO_IRQWAKEN_n register allows you to mask the expected transition on input GPIO from generating a wakeup request. The GPIO_IRQWAKEN_n register is programmed synchronously with the interface clock before any Idle mode request coming from the host processor. The GPIO_IRQWAKEN_n register is shown in Figure 24-15 and described in Table 24-13.

NOTE: In Force-Idle mode, the module wake-up feature is totally inhibited. The wake-up generation can also be gated at module level using the EnaWakeUp bit from the GPIO_SYSCONFIG register.

24.4.10 GPIO_CTRL Register

The GPIO_CTRL register controls the clock gating functionality. The DISABLEMODULE bit controls a clock gating feature at the module level. When set, this bit forces the clock gating for all internal clock paths. Module internal activity is suspended. System interface is not affected by this bit. System interface clock gating is controlled with the AUTOIDLE bit in the system configuration register (GPIO_SYSCONFIG). This bit is to be used for power saving when the module is not used because of the multiplexing configuration selected at the chip level. This bit has precedence over all other internal configuration bits. The GPIO_CTRL register is shown in Figure 24-17 and described in Table 24-15.

Figure 24-17. GPIO_CTRL Register

		0	Functional clock is interface clock.
		1h	Functional clock is interface clock divided by 2.
		2h	Functional clock is interface clock divided by 4.
		3h	Functional clock is interface clock divided by 8.
0	DISABLEMODULE		Module Disable
		0	Module is enabled, clocks are not gated.
		1	Module is disabled, clocks are gated.

24.4.11 GPIO_OE Register

The GPIO_OE register is used to enable the pins output capabilities. At reset, all the GPIO related pins are configured as input and output capabilities are disabled. This register is not used within the module, its only function is to carry the pads configuration. When the application is using a pin as an output and does not want interrupt/wake-up generation from this pin, the application can/has to configure properly the Wakeup Enable and the Interrupt Enable registers. The GPIO_OE register is shown in Figure 24-18 and described in Table 24-16.

24.4.12 GPIO_DATAIN Register

The GPIO_DATAIN register is used to register the data that is read from the GPIO pins. The GPIO_DATAIN register is a read-only register. The input data is sampled synchronously with the interface clock and then captured in the GPIO_DATAIN register synchronously with the interface clock. So, after changing, GPIO pin levels are captured into this register after two interface clock cycles (the required cycles to synchronize and to write the data). The GPIO_DATAIN register is shown in Figure 24-19 and described in Table 24-17.

NOTE: When the AUTOIDLE bit in the system configuration register (GPIO_SYSCONFIG) is set, the GPIO_DATAIN read command has a 3 OCP cycle latency due to the data in sample gating mechanism. When the AUTOIDLE bit is not set, the GPIO_DATAIN read command has a 2 OCP cycle latency.

24.4.13 GPIO_DATAOUT Register

The GPIO_DATAOUT register is used for setting the value of the GPIO output pins. Data is written to the GPIO_DATAOUT register synchronously with the interface clock. This register can be accessed with direct read/write operations or using the alternate 'Set/Clear' feature. This feature enables to set or clear specific bits of this register with a single write access to the set data output register (GPIO_SETDATAOUT) or to the clear data output register (GPIO_CLEARDATAOUT) address. The GPIO_DATAOUT register is shown in Figure 24-20 and described in Table 24-18.

24.4.14 GPIO_LEVELDETECT0 Register

The GPIO_LEVELDETECT0 register is used to enable/disable for each input lines the low-level (0) detection to be used for the interrupt request generation. The GPIO_LEVELDETECT0 register is shown in Figure 24-21 and described in Table 24-19.

NOTE: Enabling at the same time high-level detection and low-level detection for one given pin makes a constant interrupt generator.

Figure 24-21. GPIO_LEVELDETECT0 Register

25.1 Introduction

25.2 Integration

25.3 Functional Description

This document describes the booting functionality of the device, referred hereafter as ROM Code. The booting functionality covers the following features:

Memory Booting: Booting the device by starting code stored on permanent memories like flash-memory or memory cards. This process is usually performed after either device cold or warm reset.

Peripheral Booting: Booting the device by downloading the executable code over a communication interface like UART, USB or Ethernet. This process is intended for flashing a device.

The device always starts up in secure mode. The ROM Code takes care of early initialization. The ROM code switches the device into public mode. Hence the Public ROM Code provides run-time services for cache maintenance.

The document doesn't cover in details the security related aspects. This is covered separately in the Secure ROM specification. It is intended for all who design systems based on this device and develop boot loader images and flashing tools.

25.3.1 Device Types

This device has two types of production devices: a High Secure (**HS**) device and a General Purpose (**GP**) device. The fundamental difference between these two types of production devices is the approach to secure booting. The **HS Device** doesn't allow booting code which is not trusted (authenticated, that is digitally signed and checked for integrity). On the other hand the **GP Device** has its security features disabled and does not require signed code for booting the device. Image formats are different depending on the device type and described in this document.

25.3.2 Architecture

The architecture of the Public ROM Code is shown in Figure 25-1. It is split into three main layers with a top-down approach: high-level, drivers, and hardware abstraction layer (HAL). One layer communicates with a lower level layer through a unified interface.

The high level layer is in charge of the main tasks of the Public ROM Code: watchdog & clocks configuration and main booting routine.

The drivers layer implements the logical and communication protocols for any booting device in accordance with the interface specification.

Finally the HAL implements the lowest level code for interacting with the hardware infrastructure IPs. End booting devices are attached to device IO pads.

Figure 25-1. Public ROM Code Architecture

25.3.3 Functionality

Figure 25-2 illustrates the high level flow for the Public ROM Code booting procedure. On this device the Public ROM Code starts upon completion of the secure startup (performed by the Secure ROM Code). The ROM Code then performs platform configuration and initialization as part of the public start-up procedure.

The booting device list is created based on the **SYSBOOT** pins. A booting device can be a **memory booting device** (soldered flash memory or temporarily booting device like memory card) or a **peripheral interface** connected to a host.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

The main loop of the booting procedure goes through the booting device list and tries to search for an image from the currently selected booting device. This loop is exited if a valid booting image is found and successfully executed or upon watchdog expiration.

The image authentication procedure is performed prior to image execution on an **HS Device**. Failure in authentication procedure leads to branching to a “dead loop” in Secure ROM (waiting for a watchdog reset).

Figure 25-2. Public ROM Code Boot Procedure

25.3.4 Memory Map

25.3.4.1 Public ROM Memory Map

The on-chip ROM memory map is shown in Figure 25-3. The bottom part of the physical ROM contains the Secure ROM Code. The upper part holds the Public ROM Code. The Public ROM Code mapping consists in the following:

- Exception vectors
- CRC
- Dead loops collection
- Code and const data sections
- ROM Version

Figure 25-3. ROM Memory Map

Public ROM Exception Vectors

Table 25-1 lists the Public ROM exception vectors. The reset exception is redirected to the Public ROM Code startup. Other exceptions are redirected to their RAM handlers by loading appropriate addresses into the PC register.

Table 25-1. ROM Exception Vectors

Address	Exception	Content
20000h	Reset	Branch to the Public ROM Code startup
20004h	Undefined	PC = 4030D004h
20008h	SWI	PC = 4030D008h
2000Ch	Pre-fetch abort	PC = 4030D00Ch
20010h	Data abort	PC = 4030D010h
20014h	Unused	PC = 4030D014h
20018h	IRQ	PC = 4030D018h
2001Ch	FIQ	PC = 4030D01Ch

Public ROM Code CRC

The Public ROM Code CRC is calculated as 32 bit CRC code (CRC-32-IEEE 802.3) for the address range 20000h – 2BFFFh. The four bytes CRC code is stored at location 20020h.

Dead Loops

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Built-in dead loops are used for different purposes as shown in below Table 25-2. All dead loops are branch instructions coded in ARM mode. The fixed location of these dead loops facilitates debugging and testing. The first seven dead loops are default exception handlers linked with RAM exception vectors. The dead loops might be called directly from the user code. However there exists a special function which can be called from ROM Code in order to execute a dead loop. The function is an assembly code in ARM mode which takes the dead loop address from R0 register. The main purpose of the function is to go a dead loop, till the watchdog expires and resets the device, when device is **GP** type. In case of **HS Device** the function branches to the requested dead loop. The function is located at address 200C0h. In addition the function clears global cold reset status upon issuing the global SW reset.

Table 25-2. Dead Loops

Address	Purpose
20080h	Undefined exception default handler
20084h	SWI exception default handler
20088h	Pre-fetch abort exception default handler
2008Ch	Data abort exception default handler
20090h	Unused exception default handler
20094h	IRQ exception default handler
20098h	FIQ exception default handler
2009Ch	Validation tests PASS
200A0h	Validation tests FAIL
200A4h	Reserved
200A8h	Image not executed or returned.
200ACh	Reserved
200B0h	Reserved
200B4h	Reserved
200B8h	Reserved
200BCh	Reserved

Code

This space is used to hold code and constant data.

Public ROM Code Version

The ROM Code version consists of two decimal numbers: major and minor. It can be used to identify the ROM Code release version in a given IC (e.g., useful to identify an IC version). The ROM Code version is a 32bits hexadecimal value located at address 2BFFCh.

25.3.4.2 Public RAM Memory Map

The Public ROM Code makes use of the on chip RAM module connected to the L3 interconnect (further referred as **L3 RAM** in this document). Its usage is shown in Figure 25-4. The Public RAM memory map ranges from address 402F0000h to 4030FFFFh on a **GP Device**.

Figure 25-4. Public RAM Memory Map

RAM Exception Vectors

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

The RAM exception vectors enable a simple means for redirecting exceptions to custom handlers. Table 25-3 shows content of the RAM space reserved for RAM vectors. The first seven addresses are ARM instructions which load the value located in the subsequent seven addresses into the PC register. Theses instructions are executed when an exception occurs since they are called from the ROM exception vectors. Undefined, SWI, Unused and FIQ exceptions are redirected to a hardcoded dead loop. Pre-fetch abort, data abort, and IRQ exception are redirected to pre-defined ROM handlers. User code can redirect any exception to a custom handler either by writing its address to the appropriate location from 4030D024h to 4030D03Ch or by overriding the branch (load into PC) instruction between addresses from 4030D004h to 4030D01Ch.

Table 25-3. RAM Exception Vectors

Address	Exception	Content
4030D000h	Reserved	Reserved
4030D004h	Undefined	PC = [4030D024h]
4030D008h	SWI	PC = [4030D028h]
4030D00Ch	Pre-fetch abort	PC = [4030D02Ch]
4030D010h	Data abort	PC = [4030D030h]
4030D014h	Unused	PC = [4030D034h]
4030D018h	IRQ	PC = [4030D038h]
4030D01Ch	FIQ	PC = [4030D03Ch]
4030D020h	Reserved	20090h
4030D024h	Undefined	20080h
4030D028h	SWI	20084h
4030D02Ch	Pre-fetch abort	Address of default pre-fetch abort handler[(1)]
4030D030h	Data abort	Address of default data abort handler[(1)]
4030D034h	Unused	20090h
4030D038h	IRQ	Address of default IRQ handler
4030D03Ch	FIQ	20098h

(1) The default handlers for pre-fetch and data abort are performing reads from CP15 debug registers to retrieve the reason of the abort:
- In case of pre-fetch abort: the IFAR register is read from CP15 and stored into R0. The IFSR register is read and stored into the R1 register. Then the ROM Code jumps to the pre-fetch abort dead loop (20088h).
- In case of data abort: the DFAR register is read from CP15 and stored into R0. The DFSR register is read and stored into the R1 register. Then the ROM Code jumps to the data abort dead loop (2008Ch).

Tracing Data

This area contains trace vectors reflecting the execution path of the public boot. Section 25.3.13 describes the usage of the different trace vectors and lists all the possible trace codes.

Table 25-4. Tracing Data

Address	Size[bytes]	Description
4030D040h	4	Current tracing vector, word 1
4030D044h	4	Current tracing vector, word 2
4030D048h	4	Current tracing vector, word 3
4030D04Ch	4	Current copy of the PRM_RSTST register (reset reasons)
4030D050h	4	Cold reset run tracing vector, word 1
4030D054h	4	Cold reset run tracing vector, word 2
4030D058h	4	Cold reset run tracing vector, word 3
4030D05Ch	4	Reserved
4030D060h	4	Reserved
4030D064h	4	Reserved

Static Variables

This area contains the ROM Code static variables used during boot time.

25.3.5 Start-up and Configuration

25.3.5.1 ROM Code Start-up

On this device the main MPU subsystem always starts its execution in secure mode after reset due to the **TrustZone architecture** (the Secure ROM Code implements the reset handler).

The Public ROM Code is physically located at the address 20000h that is immediately next to the Secure ROM Code.

Figure 25-5. ROM Code Startup Sequence

As shown at top of Figure 25-5, the CPU jumps to the Public ROM Code reset vector once it has completed the **secure boot** initialization.

Once in public mode the CPU performs the public-side initialization and stack setup (compiler auto generated C- initialization or “scatter loading”). Then it configures the watchdog timer 1 (set to three minutes), performs system clocks configuration. Finally it jumps to the booting routine.

25.3.5.2 CPU State at Public Startup

The CPU **L1 instruction cache** and **branch prediction** mechanisms are not activated as part of the public boot process. The public vector base address is configured to the reset vector of Public ROM Code (20000h). MMU is left switched off during the public boot (hence L1 data cache off).

25.3.5.3 Clocking Configuration

The device supports the following frequencies based on SYSBOOT[15:14]

Table 25-5. Crystal Frequences Supported

SYSBOOT[15:14]	Crystal Frequency
00b	19.2 MHz
01b	24 MHz
10b	25 MHz
11b	26 MHz

The ROM Code configures the clocks and DPLLs which are necessary for ROM Code execution:

- **L3 ADPLLS** locked to provide 200MHz clocks for peripheral blocks.
- **DDR DPLL** locked to provide 400MHz.
- **MPU ADPLLS** is locked to provide 500 MHz for the A8.
- **PER ADPLLJ** is locked to provide 960MHz and 192MHz for peripheral blocks.

The Table 16 summarizes the **ROM Code default settings** for clocks. This default configuration enables all the ROM Code functionalities with minimized needs on power during boot.

Table 16: The ROM Code default clock settings

Table 25-6.

Clock	Frequency [MHz]	Source
L3_FCLK	200	CORE_CLKOUTM4
SPI_CLK	48	PER_CLKOUTM2
MMC_CLK	96	PER_CLKOUTM2
UART_CLK	48	PER_CLKOUTM2

Copyright © 2011, Texas Instruments Incorporated

DRAFT ONLY

Table 25-6. (continued)

I2C_CLK	48	PER_CLKOUTM2
MPU_CLK	500	MPU_PLL
USB_PHY_CLK	960MHz	PER_CLKDCOLDO

The DPLLs and PRCM clock dividers are configured with the ROM Code default values after cold or warm reset in order to give the same working conditions to the Public ROM Code sequence.

25.3.6 Booting

25.3.6.1 Overview

Figure 25-6 shows the booting procedure. First a **booting device list** is created. The list consists of all devices which will be searched for a booting image. The list is filled in based on the **SYSBOOT**.

Figure 25-6. ROM Code Booting Procedure

Once the booting device list is setup, the booting routine examines the devices enumerated in the list sequentially and either executes the **memory booting** or **peripheral booting** procedure depending on the **booting device type**. The memory booting procedure is executed when the booting device type is one of NOR, NAND, MMC or SPI-EEPROM. The peripheral booting is executed when the booting device type is Ethernet, USB or UART.

The memory booting procedure reads data from a memory type device. If a valid **booting image** is found and successfully read from the external memory device:

- If the device is an **HS device** then the image is **authenticated** and Initial SW **started** upon successful authentication.
- If the device is a **GP device** the Initial SW is simply **started** (no authentication involved).

The peripheral booting procedure downloads data from a host (commonly a PC) to the device device by means of Ethernet, USB or UART links. The ROM Code uses a host-slave logical protocol for synchronization. Upon successful UART, USB or Ethernet connection the host sends the image binary contents. The peripheral booting procedure is described in detail in Section 25.3.9.

If the memory or peripheral booting fails for all devices enumerated in the device list then the ROM Code gets into a loop, waiting for the watchdog to reset the system.

25.3.6.2 Device List

The ROM Code creates the **device list** based on information gathered from the **SYSBOOT configuration pins** sensed in the control module. The pins are used to index the device table from which the list of devices is extracted

25.3.6.2.1 SYSBOOT Configuration Pins

Table 16: SYSBOOT configuration pins

Reserved	reserved	**reserved**	**reserved**	11110
GP Fast external Boot	EMAC	**UART**	**reserved**	11111

The ROM Code uses the row pointed by the SYSBOOT pins value .The device list is filled in with the 1st to 4th devices.

Table 16 is the decoding table for SYSBOOT pin configuration. The following shortcuts are used in the table:

- MMC1– MMC or SD card (MMC port 1)
- MMC– MMC or SD card (MMC port 0)
- NAND / NANDI2C– NAND flash memory / read geometry from EEPROM on I2C0
- XIP / XIP w/ WAIT– NOR or other XIP device with or without wait monitoring
- UART– UART interface (UART port 0)
- EMAC– Ethernet interface (EMAC port 1)
- SPI– SPI EEPROM (SPI 0, CS0)
- USB– USB interface (USB0)

Note: For any SYSBOOT value that is selected, please be aware that the pin muxing implications. For eg, if the boot mode selected is EMAC, NAND, SPI, NANDI2C, the SOC will drive EMAC, GPMC, SPI and I2C pins, in that order, depending on which boot device finally succeeds. For specific details of the pins driven by each device, please refer the description of that boot device later in this document.

To extend the boot flow to boot from devices that are not natively supported by the ROM, SPI boot can be used. For example, if a customer wants to boot from a USB stick, the system can be configured to boot from a SPI flash, and the code for configuring the USB and booting from a USB stick can be loaded into the SPI flash. This is known as a secondary boot.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

The values mentioned in the last row and corresponding SYSBOOT[4:0]= x1111 when used on an EMULATOR device correspond to the HW assisted bypass mode booting feature offered on the device. In that case the ROM Code is fully bypassed and the device starts up from reset vector 0x0 routed to the GPMC. This feature is fully driven by HW without any SW involvement. In this configuration the SYSBOOT[9] signal selects whether the WAIT signal must be monitored on the GPMC interface. The external boot feature is not available on GP / HS production devices.

However in the case of **GP Device** a “Fast XIP boot mechanism” (as described in section 6) is provided where minimal execution is performed from ROM Code for configuring the GPMC interface and then directly jump to the code contained in the connected NOR flash device.

The NOR device must fulfill the following requirements for EMU external boot mode and GP fast XIP mode:

- Addr/Data muxed device or a non-muxed (selected using SYSBOOT[11:10]) device in connected in MUX1 configuration
- Bus width selected by SYSBOOT[8]
- CS0 chip select
- Device wait signal connected to the WAIT0 GPMC signal (if used)
- The wait monitoring enable/disable is based on the value of SYSBOOT[9]

25.3.7 Fast External Booting

25.3.7.1 Overview

The Fast External boot feature:

-
  - Is only possible on **GP Device**
  - Consists of a blind jump in ARM mode to a code located in an external XIP device connected to CS0
  - The jump is performed with minimum on-chip ROM Code execution, without configuring any PLL
  - Allows the customer to create its own booting code
  - Is set up by means of the configuration pins, see Table 16.

25.3.7.2 External Booting

Figure 25-7 shows the Fast External Boot procedure. The code does not make use of RAM and is designed for fast execution.

Figure 25-7. Fast External Boot

25.3.8 Memory Booting

25.3.8.1 Overview

The Memory Booting procedure takes care of starting an external code located in memory device types. These devices are also called **permanent booting devices** since the device uses them for booting permanently.

Figure 25-8. Memory Booting

The permanent booting devices supported are:

- MMC/SD cards
- NOR flash
- NAND flash
- SPI EEPROMs

Copyright © 2011, Texas Instruments Incorporated

There are two groups of permanent booting devices distinguished by the need of **code shadowing**. The code shadowing means copying a code from a non-directly addressable device into a location (typically a RAM area) from where the code can be executed. Devices which are directly addressable are called **eXecute In Place** (XIP) devices.

The Memory Booting flowchart is shown in Figure 25-8. The second step is about performing the shadowing of the image that is copying the image from external mass storage (non-XIP) into internal RAM. On an **HS Device**, image **authentication** and **execution** are the last steps performed. Unsuccessful authentication or return from image results in a “dead loop”. Failure in image copy results in Memory Booting returning to the main booting procedure which will select the next device for booting. The next sections detail procedures for device initialization & detection in addition to the description of the sector read routine for each supported device type. A sector is a logical unit of 512 bytes.

The detection of whether an image is present or not on a selected device is different depending on the device type:

- On an **HS Device** type a booting image is considered present when the image TOC structure begins with a known Initial SW TOC item.
- On a **GP Device** type a booting image is considered to be present when the first four bytes of the sector is not equal to 0000 0000h or FFFF FFFFh.

During the first read sector call, sectors are copied to a temporary RAM buffer. Once the image is found and destination address is known, the content of the temporary buffer is moved to the target RAM location so it is needed to re-read the first image sector. On a **GP Device** the GP header is discarded, therefore only executable code is located in RAM with the first executable instruction located at the destination address.

The Image authentication and execution is detailed in Section 25.3.11. For more information about image formats and contents, see Section 25.3.10

MMC/SD cards and NAND devices can hold up to four copies of the booting image. Therefore the ROM Code searches for one valid image out of the four if present by walking over the first four blocks of the mass storage space. Other XIP devices (NOR) use only one copy of the booting image.

25.3.8.2 XIP Memory

The ROM Code can boot directly from XIP devices. A typical XIP device is a NOR flash memory. Support for XIP devices is performed under the following assumptions:

- Uses GPMC as the communication interface
- Up to 1Gbit (128Mbytes) memories can be connected
- Both x8 and x16 data bus width
- Asynchronous protocol
- Supports address / data multiplexed mode and non-muxed mode
- GPMC clock is 50MHz
- Device connected to CS0 mapped to address 8000000h
- Wait pin signal WAIT0 monitored depending on the SYSBOOT pin configuration (XIP/XIPWAIT).
- Flexible muxing options for gpmc_a0-gpmc_a11 for non-muxed XIP devices

Depending on the SYSBOOT pins, the GPMC is configured to use the WAIT signal connected on the WAIT0 pin or not. Wait pin polarity is set to stall accessing memory when the WAIT0 pin is low. The wait monitoring is intended to be used with memories which require long time for initialization after reset or need to pause while reading data. The boot procedure from XIP device can be described as such:

- Configure GPMC for XIP device access.
- Set the image location to 8000000h
- Verify if bootable image is present at the image location.
- If the image has been found, perform authentication (**HS Device**), and start it (GP/HS).
- If the image has not been found, return from XIP booting to the main booting loop.

25.3.8.2.1 XIP Initialization and Detection

- GPMC initialization

The following figure and table describes the GPMC timing settings set for XIP boot and other address-data accessible devices (e.g. OneNAND).

Figure 25-9. GPMC XIP Timings

Table 25-8. XIP Timings Parameters

Parameter	Description	Value [clock cycles]
t_{wr}	write cycle period	17
t_{rd}	read cycle period	17
t_{CEon}	CE low time	1
t_{CEoff}	CE high time	16
t_{ADVon}	ADV low time	1
t_{ADVoff}	ADV high time	2
t_{OEon}	OE low time	3
t_{WEon}	WE low time	3
t_{rddata}	data latch time	15
t_{OEoff}	OE high time	16
t_{WEoff}	WE high time	15

The one clock cycle is 20nswhich corresponds to 50-MHz frequency.

- Device detection

There is no specific identification routine executed prior to booting from an XIP device.

25.3.8.2.2 Pins Used

The list of device pins that are configured by the ROM incase of NOR boot mode are as follows. Please note that all the pins might not be driven at boot time. The decision as to which pins need to be driven is done based on the type of NOR flash selected. **On the upper address lines, it is the board designer's responsibility to use necessary pulls so that at POR, the address lines from a12-a27 on the NOR flash are at logic 0**.

Table 25-9. Pins Used for NOR Boot

Signal name	Pin used in XIP_MUX1 mode	Pin used in XIP_MUX2 mode
cs0	gpmc_cs0	gpmc_cs0
advn_ale	gpmc_advn_ale	gpmc_advn_ale
oen_ren	gpmc_oen_ren	gpmc_oen_ren
be0n_cle	gpmc_be0n_cle	gpmc_be0n_cle
wen	gpmc_wen	gpmc_wen
wait	gpmc_wait	gpmc_wait
ad0 - ad15	gpmc_ad0 - gpmc_ad15	gpmc_ad0 - gpmc_ad15
a0	gpmc_a0	lcd_data0
a1	gpmc_a1	**lcd_data1**
a2	**gpmc_a2**	**lcd_data2**
a3	**gpmc_a3**	**lcd_data3**
a4	**gpmc_a4**	**lcd_data4**
a5	gpmc_a5	lcd_data5
a6	**gpmc_a6**	**lcd_data6**
a7	**gpmc_a7**	lcd_data7
a8	**gpmc_a8**	lcd_vsync

a10	**gpmc_a10**	lcd_pclk
a11	**gpmc_a11**	lcd_ac_bias_en

25.3.8.2.3 Sysboot Pins

Some of the SYSBOOT pins have special meanings when NOR boot is selected.

Table 25-10. Special SYSBOOT Pins for NOR Boot

SYSBOOT[n]	Description
[8] (CS0BW)	Must be 0 if 8-bit device is usedMust be 1 if 16-bit device is used
[11:10] (CS0MUX[1:0])	00b – Non-muxed device01b – A/D muxed device10b – reserved11b – reserved.

25.3.8.2.4 Image Shadowing for Non-XIP Memories

25.3.8.2.4.1 Shadowing on GP Device

The **GP Device** shadowing uses the following approach.

Figure 25-10. Image Shadowing on GP Device

25.3.8.2.5 NAND

The NAND flash memory is not XIP and requires shadowing before the code can be executed.

25.3.8.2.5.1 Features

- Uses GPMC as the communication interface
- Device from 512Mbit (64MByte)
- x8 and x16 bus width
- Support for large page size (2048 bytes + 64 spare bytes) or very large page size 4096 bytes + 128 / 218 spare bytes)
- Only supports devices where Chip Select can be de-asserted during read, program or erase cycles, without interrupting the operation
- Single Level Cell (SLC) and Multiple Level Cell (MLC) devices
- Device Identification based on ONFI or ROM table
- ECC correction : 8 bits/sector for most devices (16b/sector for devices with large spare area)
- Support for disabling ECC correction, so than the in-built ECC correction mechanisms on some NANDs can be used.
- GPMC timings adjusted for NAND access
- GPMC clock is 50MHz
- Device connected to CS0
- Wait pin signal WAITPIN0 connected to NAND BUSY output
- Four physical blocks are searched for an image. The block size depends on device.

25.3.8.2.5.2 Initialization and Detection

The initialization routine for NAND devices consists in three parts: GPMC initialization, device detection with parameters determination and finally bad block detection.

ONFI Support

The NAND identification starts with ONFI detection. For more information on ONFI standard, see [19].

GPMC Initialization

The GPMC interface is configured as such it can be used for accessing NAND devices. The address bus is released since a NAND device does not use it. The data bus width is initially set to 8 bits; and changed to 16 bits if needed after device parameters determination. The following scheme is applied since NAND devices require different timings when compared to regular NOR devices:

Figure 25-11. GPMC NAND Timings

Table 25-11. NAND Timings Parameters

Parameter	Description	Value [clock cycles]
t_{wr}	write cycle period	30
t_{rd}	read cycle period	30
t_{CEon}	CE low (not marked on the figure)	0
t_{OEon}	CE low to OE low time	7
t_{WEon}	CE low to WE low time	5
t_{rddata}	CE low to data latch time	21
t_{OEoff}	CE low to OE high time	24
t_{WEoff}	CE low to WE high time	22

Figure 25-11 and Table 25-11 describes the timings configured for NAND device access. The one clock cycle is 20 ns, which correspond to 50-MHz frequency.

Device Detection and Parameters

The ROM Code first performs an initial wait for device auto initialization (with 250ms timeout) with polling of the ready information. Then, it needs to identify the NAND type connected to the GPMC interface. The GPMC is initialized using 8 bits, asynchronous mode. The NAND device is reset (command FFh) and its status is polled until ready for operation (with 200ms timeout). The ONFI Read ID (command 90h / address 20h) is sent to the NAND device. If it replies with the ONFI signature (4 bytes) then a Read parameters page (command ECh) is sent. If the parameters page does not have the ONFI signature, then the ONFI identification fails. If the ONFI identification passes, the information shown in Table 25-12 is then extracted: page size, spare area size, number of pages per block, and the addressing mode. The remaining data bytes from the parameters page stream are simply ignored.

Table 25-12. ONFI Parameters Page Description

Offset	Description	Size (bytes)
6	Features supported	2
80	Number of data bytes per page	4
84	Number of spare bytes per page	2
92	Number of pages per block	4
101	Number of address cycles	1

If the ONFI Read ID command fails (it will be the case with any device not supporting ONFI) then the device is reset again with polling for device to be ready (with 200ms timeout). Then, the standard Read ID (command 90h / address 00h) is sent. If the Device ID (2nd byte of the ID byte stream) is recognized as being a supported device then the device parameters are extracted from an internal ROM Code table. The list of supported devices is shown in Table 25-13.

When the parameters are retrieved from the ROM table: page size and block size is updated based on 4th byte of NAND ID data. Due to inconsistency amongst different manufacturers, only devices which has been recognized to be at least 2Gb (included) have these parameters updated. Therefore, the ROM Code supports 4kB page devices but only if their size, according to the table, is at least 2Gb. Devices which are smaller than 2Gb have the block size parameter fixed to 128kB. Table 25-14 shows the 4th ID Data byte encoding used in ROM Code.

Table 25-14. 4th NAND ID Data Byte

Item	Description	I/O #

Page Size	**1kB**							**0**	**0**
	2kB							0	1
	4kB							1	0
	8kB							1	1
Cell type	2 levels					0	0		
	4 levels					0	1		
	8 levels					1	0		
	16 levels					1	1		
Block Size	64kB			0	0				
	128kB			0	1				
	256kB			1	0				
	512kB			1	1				

Reading NAND Geometry From I2C EEPROM

ROM supports a special boot mode called NANDI2C to support NAND devices whose geometry cannot be detected by the ROM automatically using methods described in the previous section (Figure 12). If this boot mode is selected, the ROM code tries to read NAND geometry from an I2C EEPROM. If the read is successful, ROM code then proceeds to next steps of NAND boot, beginning with reading bad blocks information.

Note: The NAND bus width configuration mentioned in the I2C EEPROM overrides the BUSWIDTH configuration selected by SYSBOOT pins.

The list of device pins that are configured by the ROM incase of NANDI2C boot mode. (This is in addition to the NAND boot pins described in the previous sections.)

Table 25-15. Pins Used for NANDI2C Boot for I2C EEPROM Access

Signal name	Pin Used in Device
I2C SCL	**i2c0_scl**
I2C SDA	**i2c0_sda**

ROM accesses the I2C EEPROM at I2C slave address **0x50** and reads 7 bytes starting from address offset **0x80**. The format of this (NAND geometry information) is as follows:

Table 25-16. NAND Geometry Information on I2C EEPROM

Byte address	Information	
	Upper nibble	Lower nibble
0x80	Magic Number – 0x10	
0x81	Magic Number – 0xb3	
0x82	Magic Number – 0x57	
0x83	Magic Number – 0xa6	
0x84	NAND column address (word/byte offset within a page) size in bytes, Example: 2	NAND row address (page offset) size in bytes. Example: 3

Table 25-16. NAND Geometry Information on I2C EEPROM (continued)

Byte address	Information	
0x85	Page size (2^N) exponent "N". Example (for page size of 2048): 11	Pages per block (2^N) exponent "N"Example (for number of blocks 64): 6
0x86	NAND bus width0 è 8-bit, 1 è 16-bit	ECC Type0 è No ECC, 1 è BCH8, 2 è BCH16

- ECC correction

The default ECC correction applied is BCH 8b/sector using the GPMC and ELM hardware.

For device ID codes D3h, C3h, D5h, C5h, D7h, C7h, DEh, CEh when manufacturer code (first ID byte) is 98h the Cell type information is checked in the 4th byte of ID data. If it is equal to 10b then the ECC correction applied is BCH 16b/sector.

In addition ECC computation done by the ROM can be turned off completely by using SYSBOOT[9]. This is particularly useful when interfacing with NAND devices that have built in ECC engines.

Table 25-17. ECC Configuration for NAND Boot

SYSBOOT[9]	ECC Computation
0	ECC done by ROM
1	ECC handled by NAND

Figure 25-12. NAND Device Detection

The detection procedure is described in Figure 25-12. Once the device has been successfully detected, the ROM Code changes GPMC to 16-bit bus width if necessary.

Bad Block Verification

Invalid blocks are blocks which contain invalid bits whose reliability cannot be guaranteed by the manufacturer. Those bits are identified in the factory or during the programming and reported in the initial invalid block information located in the spare area on the 1st and 2nd page of each block. Since the ROM Code is looking for an image in the first four blocks, it must detect block validity status of these blocks. Blocks which are detected as invalid are not accessed later on. Blocks validity status is coded in the spare areas of the first two pages of a block (first byte equal to FFh in 1st and 2nd pages for an 8 bits device / first word equal to FFFFh in 1st and 2nd page for a 16bits device).

Figure 25-13 depicts the invalid block detection routine. The routine consists in reading spare areas and checking validity data pattern.

Figure 25-13. NAND Invalid Blocks Detection

25.3.8.2.5.2.1 NAND Read Sector Procedure

The ROM Code reads data from NAND devices in 512 bytes sectors. The read function fails in two cases:

- The accessed sector is within a block marked as invalid
- The accessed sector contains an error which cannot be corrected with ECC

Figure 25-14 shows the read sector routine for NAND devices. The ROM Code uses normal read (command 00h 30h) for reading NAND page data.

Figure 25-14. NAND Read Sector Procedure

Page data can contain errors due to memory alteration. The ROM Code uses an ECC correction algorithm to detect and possibly correct those errors. The ECC algorithm used is BCH with capability for correcting 8b or 16b errors per sector. The BCH data is automatically calculated by the GPMC on reading each 512 bytes sector. The computed ECC is compared against ECC stored in the spare area for the corresponding page. Depending on the page size, the amount of ECC data bytes stored in the corresponding spare area

DRAFT ONLY

is different. Figure 25-15 and Figure 25-16 show the mapping of ECC data inside the spare area for respectively 2KB-page and 4KB- page devices. If both ECC data are equal then the Read Sector function returns the read 512 bytes sector without error. Otherwise the ROM Code tries to correct error(s) in the corresponding sector (this procedure is assisted by the ELM hardware) and returns the data if successful. If errors are uncorrectable, the function returns with FAIL.

Figure 25-15. ECC Data Mapping for 2 KB Page and 8b BCH Encoding

Figure 25-16. ECC Data Mapping for 4 KB Page and 16b BCH Encoding

25.3.8.2.5.2.2 Pins Used

The list of device pins that are configured by the ROM incase of NAND boot mode are as follows. Please note that all the pins might not be driven at boot time.

Table 25-18. Pins Used for NAND Boot

Signal name	Pin Used in Device
cs0	gpmc_cs0
advn_ale	gpmc_advn_ale
oen_ren	gpmc_oen_ren
be0n_cle	gpmc_be0n_cle
wen	gpmc_wen
wait	gpmc_wait
clk	gpmc_clk
ad0 - ad15	gpmc_ad0 - gpmc_ad15

25.3.8.2.5.2.3 Sysboot Pins

Some of the SYSBOOT pins have special meanings when NAND boot is selected.

Table 25-19. Special SYSBOOT Pins for NAND Boot

SYSBOOT[n]	Description
[8] (CS0BW)	Must be 0 if 8-bit NAND is usedMust be 1 if 16-bit NAND is used
[9] (CS0WAIT)	Must be 0
[11:10] (CS0MUX[1:0])	Must be 0

25.3.8.2.6 MMC / SD Cards

25.3.8.2.6.1 Overview

The ROM Code supports booting from MMC / SD cards in the following conditions:

- MMC/SD Cards compliant to [6], [9] of low and high capacities.
- MMC/SD cards connected to MMC interface #0 and #1.
- 3V VCC power supply, support for 3- or 1.8-V I/O voltages.
- Initial 1-bit MMC Mode, optional 4-bit mode, if device supports it.
- Clock Frequency: identification mode: 400 KHz; data transfer mode up to 10 MHz.
- Only one card connected to the bus.
- Raw mode, image data read directly from sectors in the user area.
- File system mode (FAT12/16/32 supported with or without Master Boot Record), image data is read from a booting file.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

25.3.8.2.6.2 System Interconnection

An MMC/SD card can be connected to the **MMC0 interface** typically through a card cage.

An eMMC/eSD/managed NAND memory device can be connected to **MMC1 interface**.

Note:

- The ROM Code does not handle the card detection feature on card cage.
- If MMC1 is used the GPMC interface is not usable, due to pin muxing options.
- MMC1 supports sector mode without querying the card.

25.3.8.2.6.3 Booting Procedure

The high level flowchart of the eMMC / eSD and MMC/SD booting procedure is depicted in Figure 25-17. The booting file is searched only in case of booting from a card. eMMC/eSD embedded memories only support raw mode.

Figure 25-17. MMC/SD Booting

25.3.8.2.6.4 Initialization and Detection

The ROM Code initializes the memory device or card connected on MMC interface using the standard High-Voltage range (3.0V). If neither memory device nor card is detected then the ROM Code carries on to the next booting device. The standard identification process and **Relative Card Address (RCA)** assignment are used. However, the ROM Code assumes that only one memory or card is present on the bus. This first sequence is done using the CMD signal which is common to SD and MMC devices.

MMC and SD standards detail this phase as **initialization phase**. Both standards differ in the first commands involved: **CMD1** and **ACMD41**. The ROM Code uses this difference in command set to discriminate between MMC and SD devices: CMD1 is supported only by the MMC standard whereas ACMD41 is only supported by SD standard. The ROM Code first sends a CMD1 to the device and gets a response only if an MMC device is connected. If no response is received then ACMD41 (ACMD41 is made out of CMD55 and ACMD41) is sent and a response is expected from an SD device. If no response is received then it is assumed that no device is connected and the ROM Code exits the MMC/SD Booting procedure with FAIL. This is detection procedure shown in Figure 25-18.

Another point to note is the difference in the arguments to CMD1 between MC0 and MMC1. At first the ROM queries the card with CMD1, ARG = 0, to get the OCR from the card. On MMC0, the response from the card is simply reflected back to the card as the argument for all subsequent CMD1, till the card is in the READY state. On MMC1, Bit30 of the response received from the card is set to 1 by the ROM, and this modified value is used as the argument for subsequent CMD1. This is done to indicate to the card that the ROM supports sector addressing. This mode might not be compatible with older (older than v4.4) versions of cards.

Figure 25-18. MMC/SD Detection Procedure

As previously mentioned the contents of an MMC/SD card may be formatted as raw binary or within a FAT filesystem.. eMMC / eSD devices only support raw mode. The ROM Code reads out raw sectors from image or the booting file within the file system and boots from it.

25.3.8.2.6.5 MMC/SD Read Sector Procedure in Raw mode

In raw mode the booting image can be located at one of the four consecutive locations in the main area: offset 0x0 / 0x20000 (128 KB) / 0x40000 (256 KB) / 0x60000 (384 KB). For this reason, a booting image shall not exceed 128KB in size. However it is possible to flash a device with an image greater than 128KB starting at one of the aforementioned locations. Therefore the ROM Code does not check the image size. The only drawback is that the image will cross the subsequent image boundary.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

The raw mode is detected by reading sectors #0, #256, #512, #768. The content of these sectors is then verified for presence of a TOC structure as described in Section 25.3.10. In the case of a **GP Device**, a Configuration Header (CH) **must** be located in the first sector followed by a **GP header**. The CH might be void (only containing a CHSETTINGS item for which the Valid field is zero). In the case of an **HS Device** the TOC must contain an "MLO" item.

25.3.8.2.6.6 MMC/SD Read Sector Procedure in FAT Mode

MMC/SD Cards may hold a FAT file system which ROM Code is able to read and process. The image used by the booting procedure is taken from a specific booting file named "MLO". This file has to be located in the root directory on an active primary partition of type FAT12/16 or FAT32. See [8] and [10] for a more detailed description of MMC/SD file system support.

An MMC/SD card can be configured either as floppy-like or hard-drive-like.

- When acting as floppy-like, the content of the card is a single file system without any Master Boot Record (MBR) holding a partition table
- When acting as hard-drive-like, an MBR is present in the first sector of the card. This MBR holds a table of partitions, one of which must be FAT12/16/32, primary and active.

According to [8], the card should always hold an MBR except for MMC cards using floppy-like file system (please refer to the CSD internal Register fields FILE_FORMAT_GRP and FILE_FORMAT in [6]). However, depending on the used operating system the MMC/SD card will be formatted either with partition(s) (using an MBR) or without. The ROM Code supports both types; this is described in the following section.

The ROM Code retrieves a map of the booting file from the FAT table. The booting file map is a collection of all FAT table entries related to the booting file (a FAT entry points to a cluster holding part of the file). The booting procedure uses this map to access any 512 byte sector within the booting file without involving ROM Code FAT module.

The sector read procedure utilizes standard MMC/SD raw data read function. The sector address is generated based on the booting memory file map collected during the initialization. Hence the ROM Code can address sectors freely within the booting file space.

25.3.8.2.6.7 FAT File system

This paragraph describes functions which are used by the ROM Code, it is not intended to fully describe the Master Boot Record and the FAT file system:

- How to recognize if a sector is the 1st sector of an MBR
- How to recognize if a sector is the 1st sector of a FAT12/16/32
- How to find the 1st cluster of the booting file
- How to buffer the booting file FAT entries.

Some memory devices which support file systems can be formatted with or without MBR, therefore the first task of the ROM Code is to detect whether or not the device is holding an MBR in the first sector.

If this is the case, an active FAT12/16/32 partition is searched in all 4 MBR partition entries, based on the Type field. If the MBR entries are not valid or if no useable partition is found then the ROM Code returns to the Booting procedure with FAIL. The Extended partitions are not checked, the booting file must reside in a primary partition.

If a partition is found then its first sector is read and used further on. If no MBR is present (in case of a floppy-like system), the first sector of the device is read and used further on.

The read sector is checked to be a valid FAT12/16 or FAT32 partition. If this fails, in case another partition type is used (i.e. Linux FS or any other) or if the partition is not valid, the ROM Code returns with FAIL.

Otherwise, the Root Directory entries are searched for a file named depending on the booting device. The Long File Names (LFN) format is not used and **only File Names in 8.3 Format are searched for**. If no valid file is found, the ROM Code returns with FAIL.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Once the file has been found, the ROM Code reads the File Allocation Table (FAT) and buffers the singly-linked chain of clusters in a FAT Buffer which will be used by the Booting Procedure to access the file directly sector by sector. For FAT12/16 and for FAT32 (valid if a specific flag has been set in the FAT32 Boot Sector), there exist multiples copies of the FAT (ROM Code supports only 2 copies). When buffering FAT entries, the 2 FATs are compared. If they are not the same, only entries from the last FAT are used. The FAT Buffer holds sector numbers and not cluster numbers. The ROM Code converts each cluster entry to one or several sector entries if applicable.

The whole process is described in Figure 25-19. Every part related to MBR or FAT12/16/32 is described in the next paragraph.

Figure 25-19. SD/MMC Booting, Get Booting File

25.3.8.2.6.7.1 Master Boot Record (MBR)

The Master Boot Record is the 1st sector of a memory device. It is made out of some executable code and 4 partition entries. The aim of such a structure is to be able to divide the hard disk in partitions mostly used to boot different systems (i.e. Microsoft Windows™, Linux, …). Its structure is described in Table 25-20 and Table 25-21. The valid partition types searched by the ROM Code are described in Table 25-22.

Table 25-20. Master Boot Record Structure

Offset	Length[bytes]	Entry Description	Value
0000h	446	Optional Code	
01BEh	16	Partition Table Entry	(see Table 25-21)

Copyright © 2011, Texas Instruments Incorporated

The way the ROM Code detects whether a sector is the 1st sector of an MBR or not is described in Figure 25-20.

The ROM Code first checks if the signature is present. Each partition entry is checked:

- If its type is set to 00h then all fields in the entry must be 00h
- The partition is checked to be within physical boundaries, i.e. the partition is located inside and it's size fits the total physical sectors.

Figure 25-20. MBR Detection Procedure

Once identified, the ROM Code gets the partition using the procedure described in Figure 25-21. The partition type is checked to be FAT12/16 or FAT32. Its state must be 00h or 80h (if there are more than one active partition the test fails). The ROM Code returns with FAIL if no active primary FAT12/16/32 could be found.

Figure 25-21. MBR, Get Partition

25.3.8.2.6.7.2 FAT12/16/32 Boot Sector

The FAT file system is made out of several parts:

- Boot Sector which holds the BIOS Parameter Block (BPB)
- File Allocation Table (FAT) which describes the use of each cluster of the partition
- Data Area which holds the Files, Directories and Root Directory (for FAT12/16, the Root Directory has a specific fixed location).

The Boot Sector is described in Table 25-23. For more details, see [12].

Note: In the following description, all the fields whose names start with BPB_ are part of the BPB. All the fields whose names start with BS_ are part of the Boot Sector and not really part of the BPB (not mandatory), they are not used at all by the ROM Code.

Table 25-23. FAT Boot Sector

Offset	Length[bytes]	Name	Description
0000h	3	BS_jmpBoot	Jump Instruction to Boot Code (not used)
0003h	8	BS_OEMName	Name of the System which created the partition
000Bh	2	BPB_BytsPerSec	Counts of Bytes per sector (usually 512)
000Dh	1	BPB_SecPerClus	Number of sectors per allocation unit
000Eh	2	BPB_RsvdSecCnt	Number of reserved sectors for the Boot SectorFor FAT12/16 is 1, for FAT32, usually 32
0010h	1	BPB_NumFATs	Number of copies of FAT, usually 2
0011h	2	BPB_RootEntCnt	For FAT12/16, number of 32 bytes entries in the Root Directory (multiple of BPB_BytsPerSec/32)For FAT32 this value is 0
0013h	2	BPB_TotSec16	Total Count of sectors on the volume. If the size is bigger than 10000h or for FAT32, this field is 0 and BPB_TotSec32 holds the value
0015h	1	BPB_Media	Media Type, usually F8h: fixed, non-removable
0016h	2	BPB_FATSz16	For FAT12/16, size in sectors of one FATFor FAT32, holds 0
0018h	2	BPB_SecPerTrk	Number of sectors per track, 63 for SD/MMC
001Ah	2	BPB_NumHeads	Number of heads, 255 for SD/MMC

Table 25-23. FAT Boot Sector (continued)

Offset		Length[bytes]	Name	Description	
001Ch		4	BPB_HiddSec	Number of sectors preceeding the partition	
0020h		4	BPB_TotSec32	Total Count of sectors on the volume. If the size is smaller than 10000h (for FAT12/16), this field is 0 and BPB_TotSec16 is valid	
FAT12/16	0024h	1	BS_DrvNum	Drive Number	
	0025h	1	BS_Reserved1	00h	
	0026h	1	BS_BootSig	Extended Boot Signature 29h. Indicates that the following 3 fields are present	
	0027h	4	BS_VolID	Volume Serial Number	
	002Bh	11	BS_VolLab	Volume Label	
	0036h	8	BS_FilSysType	File system Type: “FAT12”, “FAT16”, “FAT32”.Note: This field is not mandatory (i.e BS_) therefore it cannot be used to indentify the partition type.	
FAT32	0024h	4	BPB_FATSz32	Size in sectors of one FAT. Field BPB_FATSz16 must be 0	
	0028h	2	BPB_ExtFlags	FAT Flags:	
				[7]:	0=FAT is mirrored; 1=Only one FAT is used
				[3:0]:	Number of used FAT if no mirroring used
	002Ah	2	BPB_FSVer	File system Version Number	
	002Ch	4	BPB_RootClus	First Cluster number of the Root Directory	
	0030h	2	BPB_FSInfo	Sector number of FSINFO Structure in the reserved-area, usually 1	
	0032h	2	BPB_BkBootSec	If non-zero, indicates the sector number in the reserved-area of a copy of the Boot Sector	
	0034h	12	BPB_Reserved	Reserved, set to 00h	
	0040h	1	BS_DrvNum	Drive Number	
	0041h	1	BS_Reserved1	00h	
	0042h	1	BS_BootSig	Extended Boot Signature 29h. Indicates that the following 3 fields are present	
	0043h	4	BS_VolID	Volume Serial Number	
	0047h	11	BS_VolLab	Volume Label	
	0052h	8	BS_FilSysType	File system Type: “FAT12”, “FAT16”, “FAT32”.Note: This field is not mandatory (i.e BS_) therefore it cannot be used to indentify the partition type.	
01FEh		2	BPB_Signature	AA55h	

To check whether or not a sector holds a valid FAT12/16/32 partition, only fields starting with BPB can be checked as they are mandatory. The fields starting from offset 0024h to 01FDh cannot be used for the check as they will differ if using FAT12/16 or FAT32. The procedure is described in Figure 30. First the ROM Code checks if the *BPB_Signature* is equal to AA55h. Then it checks some fields which must have some specific values (*BPB_BytsPerSec, BPB_SecPerClus, BPB_RsvdSecCnt, BPB_NumFATs, BPB_RootEntCnt*) If the geometry of the device is known (valid CHS for device size < 4Gbytes) then it is compared against *BPB_SecPerTrk* and *BPB_NumHeads* fields. If an MBR was found before, the partition size is also checked:

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

The field *BPB_ToSec16* is used if the total number of sectors is below 65518 (in this case *BPB_TotSec32*=0), otherwise *BPB_TotSec32* is used (*BPB_TotSec16*=0). The partition sector offset is also checked: *BPB_HiddSec = MBR_Partition_Offset* (if this value is not 0 as some operating systems do not update this field correctly). The last step is to decide which type of FAT file system it is. The ROM Code computes the number of clusters in the Data Area part of the partition:

Where *Nb clusters* is given by the size of the Data Area:

Figure 25-22. FAT Detection Procedure

25.3.8.2.6.7.3 FAT12/16/32 Root Directory

The next task for the ROM Code is to find the booting file named “MLO” inside the Root Directory of the FAT12/16/32 file system. The file is not searched in any other location.

For a FAT12/16 file system, the Root Directory has a fixed location which is cluster 0. For a FAT32 file system, its cluster location is given by *BPB_RootClus*. The general formulae to find the sector number (relative to device sector 0, not partition sector 0) of a cluster is given by:

$$Cluster_{sector} = BPB_RsvdSecCnt + BPB_NumFATs \times BPB_FATSz + Cluster \times BPB_SecPerClus$$

Note: BPB_FatSz is BPB_FatSz16 for FAT12/16 or BPB_FatSz32 for FAT32

Note: the *BPB_HiddSec* field can contain 0 even though the FAT file system is located somewhere other than on sector 0 (floppy-like). The ROM Code actually uses the partition offset taken from the MBR instead of this field which can be wrong. If no MBR was found (floppy-like) the value 0 is used.

Each entry in the Root Directory is 32 bytes long and hold information about the file, i.e. filename, date of creation, rights, cluster location etc. This is described in Table 25-24.

The ROM Code checks each entry in the Root Directory until either the booting file is found or the entry is empty (first byte is 00h) or when the end of the Root Directory has been reached. Entries with ATTR_LONG_NAME attribute (LFN) and with first byte at E5h (erased file) are ignored. When found, the first cluster offset of the file is read from the DIR_FstClusHi/DIR_FstClusLo fields.

There is a slight difference between FAT12/16 and FAT32 when handling the Root Directory. On FAT12/16, this directory has a fixed location (see above) and length fixed by *BPB_RootEntCnt* which is the total number of 32 bytes entries. Handling this directory is therefore straight forward. On FAT32, the Root Directory is like a standard file, the File Allocation Table (FAT) has to be used in order to retrieve each sector of the Directory. The way the FAT is handled is described in the next paragraph.

Table 25-24. FAT Directory Entry

Offset	Length[bytes]	Name	Description	
0000h	11	DIR_Name	Short Name (8+3)	
000Bh	1	DIR_Attr	File Attributes:	
			ATTR_READ_ONLY	01h
			ATTR_HIDDEN	02h
			ATTR_SYSTEM	04h
			ATTR_VOLUME_ID	08h
			ATTR_DIRECTORY	10h
			ATTR_ARCHIVE	20h
			ATTR_LONG_NAME	ATTR_READ_ONLY | ATTR_HIDDEN | ATTR_SYSTEM | ATTR_VOLUME_ID
000Ch	1	DIR_NTRes	Reserved, set to 00h	
000Dh	1	DIR_CrtTimeTenth	Millisecond stamp at file creation	
000Eh	2	DIR_CrtTime	Time file was created	
0010h	2	DIR_CrtDate	Date file was created

Table 25-24. FAT Directory Entry (continued)

Offset	Length[bytes]	Name	Description
0014h	2	DIR_FstClusHi	High word of this entry's first cluster number
0016h	2	DIR_WrtTime	Time of last write
0018h	2	DIR_WrtDate	Date of last write
001Ah	2	DIR_FstClusLo	Low word of this entry's first cluster number
001Ch	4	DIR_FileSize	File size in bytes

25.3.8.2.6.7.4 FAT12/16/32 File Allocation Table

The ROM Code needs to read the FAT in order to retrieve sectors either for the booting file or for the Root Directory (in case the file system is FAT32).

There can be multiple copies of the FAT inside the file system (ROM Code supports only 2) located after the Boot Sector:

$FATn_{sector} = BPB_HiddSec+BPB_RsvdSecCnt+BPB_FatSz \times n$

Its size is given by *BPB_FATSz16* or *BPB_FATSz32*. The ROM Code checks each copy of the FAT if identical. In case the values are different, the ROM Code uses the value from the last FAT copy.

With FAT32 file system, the copy system can be disabled according to a flag located in *BPB_ExtFlags[7]*. If this flag is set then FAT *BPB_ExtFlags[3:0]* is used. In this case no verification is made by the ROM Code with other copies of FAT.

The FAT is a simple array of values each refering to a cluster located in the Data Area. One entry of the array is 12, 16 or 32 bits depending on the file system in use.

The value inside an entry defines whether the cluster is being used or not and if another cluster has to be taken into account. This creates a singly-linked chain of clusters defining the file. The meaning of an entry is described in Table 25-25.

Note: For compatibility reasons, clusters 0 and 1 are not used for files and those entries must contain FF8h and FFFh (for FAT12); FFF8h and FFFFh (for FAT16); ?FFFFFF8h and ?FFFFFFFh (for FAT32).

Table 25-25. FAT Entry Description

FAT12	FAT16	FAT32	Description
000h	0000h	?0000000h	Free Cluster
001h	0001h	?0000001h	Reserved Cluster
002h-FEFh	0002h-FFEFh	00000002h-?FFFFFEFh	Used Cluster; value points to next cluster
FF0h-FF6h	FFF0h-FFF6h	?FFFFFF0h-?FFFFFF6h	Reserved values
FF7h	FFF7h	?FFFFFF7h	Bad Cluster
FF8h-FFFh	FFF8h-FFFFh	?FFFFFF8h-?FFFFFFFh	Last Cluster in File

Note: FAT32 uses only bits [27:0], the upper 4 bits are usually 0 and should be left untouched.

When accessing the Root Directory for FAT32, the ROM Code just starts from the Root Directory Cluster entry and follows the linked chain to retrieve the clusters.

When the booting file has been found, the ROM Code buffers each FAT entry corresponding to the file in a sector way. This means each cluster is translated to one or several sectors depending on how many sectors are in a cluster (*BPB_SecPerClus*). This buffer is used later on by the booting procedure to access the file.

25.3.8.2.6.8 Pins Used

The list of device pins that are configured by the ROM incase of MMC boot mode are as follows. Please note that all the pins might not be driven at boot time.

25.3.8.2.7 SPI

SPI EEPROMs or SPI flashes have an EEPROM or NOR flash backend and they connect to the device using the serial SPI protocol.

These typically devices operate in three stages – the command stage, the address stage and the data transfer stage. The command is usually an 8 bit value followed by the address (depending on the size of the device) followed by the data to be read or written.

Because of the need for fewer pins, these devices are comparatively inexpensive, easy for board layout, and are the devices of choice when cost, complexity and form factor are critical considerations.

25.3.8.2.7.1 Features

- Supports 12-MHz clock (50% duty cycle)
- Supports only SPI Mode 3 (clock polarity = 1, clock phase = 1)
- Supports only 24 bit addressable EEPROMs
- Supports only 4-pin SPI mode (CS, CLK, Serial Input, Serial Output)
- The boot devices must be connected to chip select 0 and must support the read command (03h)
- The boot image is copied into internal memory and then executed.

25.3.8.2.7.2 Initialization and Detection

The ROM Code initializes the SPI controller, pin muxing and clocks for communicating with the SPI device. The controller is initialized in Mode 3 and the clock is setup to operate at 12 MHz. There is no specific device identification routine that is executed by the ROM code to identify whether a boot device is preset or not. If no SPI device is present, the sector read will return only 0xFFFFFFFF and the SPI boot will be treated as failed.

25.3.8.2.7.3 SPI Read Sector Procedure

The ROM Code reads SPI data from the boot device in 512 byte sectors. For each call to the SPI Read Sector routine, the SPI Read Command (0x03) is sent along with the 24 bit start address of the data to be read.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

Form the next iteration onwards, a dummy value is transmitted on the master out line and the data is received on the master in line. This needs to be done because SPI protocol always operated in full duplex mode. The dummy data transmitted by the ROM is the Read Command appended to the start address. The data from the boot device is received MSB first.

As the A8 is a little-endian processor, and SPI operates in a big-endian format, this means that while writing to the flash, care needs to be taken to write the image in a big-endian format. This way we can avoid doing the endian conversion at boot time, thus improving boot performance.

25.3.8.2.7.4 Pins Used

The list of device pins that are configured by the ROM incase of SPI boot mode are as follows. Please note that all the pins might not be driven at boot time.

Table 25-28. Pins Used for SPI Boot

Signal name	Pin Used in Device
cs	spi0_cs0
miso	spi0_d0
mosi	spi0_d1
clk	spi0_sclk

25.3.8.3 Blocks and Sectors Search Summary

Table 25-29 summarizes numbers of blocks and sectors which are searched during the memory booting from devices requiring image shadowing. NAND is organized with blocks, which are erasable units.

Table 25-29. Blocks and Sectors Searched on Non-XIP Memories

Memory	Maximum Number of Blocks Checked	Number of Sectors Searched
NAND	first 4	Number of sectors in one block[(1)]
SPI, eMMC/eSD and MMC/SD cards (raw mode)	first 4	1

(1) Depends on NAND geometry

Regarding MMC/SD card booting in FAT mode, the file system area is searched for one file.

25.3.9 Peripheral Booting

25.3.9.1 Overview

The ROM Code can boot from four different peripheral interfaces:

- EMAC: 1000/100/10 Mbps Ethernet, using standard TCP/IP network boot protocols BOOTP and TFTP
- PCIe: Two lanes @250 MB/s
- USB: Full speed, client mode
- UART: 115.2Kbps, 8 bits, even parity, 1 stop bit, no flow control

The purpose of booting from a **peripheral interface** is to download a **boot image** from an external host (typically a PC). This booting method is mostly used for programming flash memories connected to the device (e.g. in the case of initial flashing, firmware update or servicing).

25.3.9.2 Boot Image Location and Size

The boot image is downloaded directly into internal RAM at the location 0x402F0000 on GP devices and 0x40300000h on HS devices. The maximum size of downloaded image is 110 KB.

25.3.9.3 Peripheral Boot Procedure Overview

Figure 25-23. Peripheral Booting Procedure

25.3.9.4 EMAC Boot Procedure

25.3.9.4.1 Device Initialization

- EMAC boot uses the CPGMAC port 1 of the device.
- Supports connection to external Ethernet PHY using the MII, RMI, RGMII and MDIO pins, based on SYSBOOT pin settings.
- Device uses EFUSE register MAC_ID0 for Ethernet MAC address of the device.
- Device detects if the PHY is alive on the MDIO interface and
  - Reads the STATUS register to check if Ethernet link is active
  - Reads the CONTROL register to detect the auto-negotiated mode of operation
    - Is the mode full-duplex or half duplex
    - Speed of operation, 1000/100/10 Mbps.
  - Waits for 3.5s for auto negotiation to complete before timing out.

25.3.9.4.2 BOOTP (RFC 951)

The device then proceeds to obtain the IP and Boot information using BOOTP protocol. The device prepares and broadcasts the BOOTP message that has the following information:

- Device MAC address in “chaddr” field – to uniquely identify the device to the server.
- “vender-class-identifier” option number 60 (RFC 1497, RFC 1533). Servers could use this information to identify the device type. The value present is "**DM816x ROM v1.0**"
- “”Client-identifier” option number 61 (RFC 1497, RFC 1533). This has the **ASIC-ID** structure which contains additional info for the device.

The device then expects a BOOTP response that provides the following information for the booting to proceed

- Device IP address from “yiaddr” field
- Subnetmask from extended option 1 (RFC 1497, RFC 1533)
- Gateway IP from extended option number 3 (RFC 1497, RFC 1533) or from “giaddr” field of BOOTP response.
- Boot image filename from “file” field
- TFTP server IP address from the “siaddr” field

Timeouts and retries

- Exponentially increasing timeouts starting from 4s, doubling for each retry.
- 5 retries

25.3.9.4.3 TFTP (RFC 1350)

After a successful BOOTP completion, the device initiates the TFTP download of the boot image into SRAM. The device has the capability to reach TFTP server within the local subnet or outside, though the gateway.

Timeouts and retries:

- Timeout of 1s to receive a response for the READ request
- 5 retries for the READ request
- Retries are managed by server once data transfer starts (server re-sends a data packet if the ACK was not received within a timeout value)
- Device has a 60s timeout to complete the data transfer, to handle the scenario if the server dies in the

25.3.9.5 UART Boot Procedure

25.3.9.5.1 Device Initialization

- UART boot uses UART0.
- UART0 is configured to run at 115200 baud, 8-bits, even parity, 1 stop bit and no flow control.

25.3.9.5.2 Boot Image Download

- UART boot uses x-modem client protocol to receive the boot image.
- Utilities like hyperterm, teraterm, minicom can be used on the PC side to download the boot image to the board
- With x-modem packet size of 1K throughout is roughly about 4KBytes/Sec.
- The ROM code will ping the host 10 times in 3s to start x-modem transfer. If host does not respond, UART boot will timeout.
- Once the transfer has started, if the host does not send any packet for 3s, UART boot will time out
- If the delay between two consecutive bytes of the same packet is more than 2ms, the host is requested to re-transmit the entire packet again
- Error checking using the CRC-16 support in x-modem. If an error is detected, the host is requested to re-transmit the packet again.

25.3.9.5.3 Pins Used

The list of device pins that are configured by the ROM incase of UART boot mode are as follows. Please note that all the pins might not be driven at boot time.

Table 25-34. Pins Used for UART Boot

Signal name	Pin Used in Device
rx	uart0_rxd

25.3.9.6 USB Boot Procedure

25.3.9.6.1 Device Initialization

The ROM Code supports booting from the USB interface under the following conditions:

- Using the High Speed USB OTG (USBOTGHS) IP through USB0 interface.
- USB operates in Full Speed, Client mode.
- USB will operate only in device powered mode.
- **Integrated transceiver** (through UTMI).
- The enumeration default timeout is **3s** (Timeout Usb).

Even though using an OTG capable hardware, the ROM Code does not handle any OTG specific feature.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

25.3.9.6.1.1 Overview

In case of boot from USB is chosen by the SYSBOOT pin configuration:

- The USBOTGHS hardware and PRCM clocks are configured for UTMI mode
- The ROM Code continues with the USB procedure only if the USB cable is detected present (i.e. VBUS is detected at transceiver level and communicated as such through the UTPI traffic). If not, the initialization procedure is aborted.
- The ROM code implements the RNDIS class driver
- From users perspective, USB boot is indistinguishable from Ethernet boot.
- The USB initialization procedure is shown in Figure 25-24.

Figure 25-24. USB Initialization Procedure

25.3.9.6.1.2 Enumeration Descriptors

The Device Descriptor parameters which are used during enumeration are listed in the following table. The default Vendor ID and Product ID can be automatically overridden by the customer by programming the Efuses that are used to store these values.

Table 25-35. Customized Descriptor Parameters

Parameter	Size [bytes]	TI Default Values
Device ID code	2	0000h
Device Class	1	02h
Device Sub-Class	1	FFh
Device Protocol	1	FFh
Manufacturer	String	“Texas Instruments”
Product	String	“USBRNDIS”
Serial number	String	“N/A”

.

25.3.9.6.2 Image Download Procedure

- The device supports USB client boot only.
- The ROM implements as RNDIS class driver, so the device enumerates as an ethernet port.
- Standard RNDIS drivers present on Linux and Windows are picked up during the enumeration, no special drivers need to be installed.
- Once the enumeration is complete, the customer can download the boot image using any standard TFTP server application.

Figure 25-25. Image Transfer for USB Boot

25.3.9.6.3 Pins Used

The list of the device pins that are configured by the ROM incase of USB boot mode are as follows. Please note that all the pins might not be driven at boot time.

25.3.9.7 ASIC ID structure

The ASIC ID size is 58 Bytes for UART and 81 Bytes for others. The fields of this structure are unused. This structure is included purely for legacy purposes.

25.3.10 Image Format

25.3.10.1 Overview

All preceding sections describe how the ROM Code searches and detects a boot image from a memory or a peripheral device type. This chapter describes the format of the boot image itself.

A boot image is basically made out of two major parts:

- The software to execute (with keys and certificate in case of **HS Device**).
- A header containing the destination address and size of the image for non XIP memory devices

The mandatory section of a boot image contains the software which will be loaded into the memory and executed (if correctly authenticated in case of **HS Device**). An overview of the image formats is shown in Figure 25-26:

Figure 25-26. Image Formats on GP and HS Devices

a) GP non - XIP Memory Booting

Used for memories which require shadowing (e.g. MMC). Image must begin with a GP header which contains information on image size and destination address.

b) GP Peripheral Booting and XIP Memory Booting

When memory device is of XIP type (e.g. NOR) the GP header is not needed and the image can contain code for direct execution. . The same image format is used for peripheral booting (where the code is transferred to internal RAM).

c) HS Memory and Peripheral Booting

An HS image always begins with a TOC which points to HS image items. A TOC and items (fits in one sector) can be concatenated at top of the secure image. Items can be located in any order in the image. This format is discussed in detail in section 3.3.

-
-

25.3.10.2 Image Format for GP Device

For a **GP Device** there is no security involved and therefore neither keys nor certificates are needed in the boot image.

When the booting memory device is non-XIP (e.g. MMC) the image must contain a small header (referred as GP header) with the size of the software to load and the destination address where to store it.

The GP header is not needed when booting from an XIP memory device (e.g. NOR) or in case of peripheral booting. In this case, the peripheral or memory booting image starts directly with executable code.

Table 25-37. GP Device Image Format

Field	non XIP device	XIP device	Size[bytes]	Description
	Offset	Offset		
Size	0000h	-	4	Size of the image
Destination	0004h	-	4	Address where to store the image / code entry point
Image	0008h	0000h	x	Executable code

Copyright © 2011, Texas Instruments Incorporated

DRAFT ONLY

Note: the “Destination” address field stands for both:

- Target address for the image copy from the non-XIP storage to the target XIP location (e.g., internal RAM or SDRAM)
- Entry point for image code

In other words the user must take care to locate the code entry point to the target address for image copy.

25.3.10.3 Image Format for HS Device

A signed **HS Device** image consists of various sub-images with the associated certificates needed for authentication purposes.

The minimal HS image must at least contain:

- The Table of Content (TOC)
- The Public Keys Certificate
- The Primary Protected Application (PPA) with its Certificate
- The Initial SW with its Certificate

Additional sub-images may be embedded within the image:

- R&D Certificate
- CH items

Figure 25-27 illustrates the structure of a generic image with mandatory and optional sub-images items.

Figure 25-27. Image Structure

25.3.10.3.1 Table of Contents

The TOC is 512 bytes long and consists of a maximum of 16 TOC items (32 bytes long each), located one after the other. If the number of TOC items is less than 16, the TOC item after the last used TOC item must be filled by FFh. Each TOC item contains information required by the ROM Code such as item location, size and name, as illustrated in Figure 25-28 and Table 25-38.

Figure 25-28. TOC Structure

Table 25-38. TOC Item Fields

Offset	Field	Size[bytes]	Description
0000h	Start	4	Offset from the start address of TOC to the actual address of sub image.
0004h	Size	4	Size of sub image.
0008h	Flags	4	Reserved
000Ch	Align	4	Reserved
0010h	Load Address	4	For an Initial SW TOC item during Memory Booting this field is the target address for item copy.It is ignored in other cases.
0014h	Filename	12	12 character long name of sub image, including the zero (‘\0’) terminator.

The ROM Code recognizes sections pointed to by the TOC based on the filename as described in Table 25-39:

- The ‘X-LOADER’, ‘2ND', ‘MLO’, or ‘ULO’ section contains the Initial Software
- The ‘KEYS’ section contains the Public Keys Certificate, which must be imported in the Secure RAM for subsequent authentication.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

- The ‘R&D’ section contains the R&D Certificate, which must be authenticated before being used by the ROM Code in order to activate or deactivate debug features. Note: If Authentication fails for R&D the whole Authentication process is not stopped, only debug features are not activated.
- The ‘PRIMAPP’ section contains the PPA and its Certificate, which must be imported in the Secure RAM for subsequent authentication. If the Certificate is successfully authenticated, the PPA can be executed.
- Optionally, TOC may contain CH sections. The “CHSETTINGS” is a mandatory section of CH and is used to recognize CH presence.

Table 25-39. Filenames in TOC

Filename	Description
X-LOADER	Bootstrap
2ND	Secondary loader (Peripheral booting)
MLO	MMC/SD Loader (Memory booting)
ULO	Alternative filename used for Secondary Loader via USB (Peripheral booting)
KEYS	Contains the Public Keys Certificate
R&D	Contains the R&D Certificate
PRIMAPP	Contains the PPA and its Certificate
CHSETTINGS	Configuration Header general setting item. This item is mandatory for CH
CHRAM	Configuration Header EMIF item
CHFLASH	Configuration Header GPMC item
CHMMCSD	Configuration Header MMC/SD item

25.3.10.3.2 Certificates

For a detailed description of certificates and other remaining items of an HS image, see.

25.3.11 Authentication and Execution

25.3.11.1 Overview

One of the early steps of the Public ROM Code execution is to search for a boot image from the requested medium (configured by the SYSBOOT pins) and copy it to RAM if needed. If the device is of GP type and boot interface is non-XIP then the image is simply copied to the provided destination address (internal or external RAM) and then executed. If the boot interface is of XIP type then the image copy is not needed and execution is directly given to the XIP memory. In the case of an **HS Device** the next step of the booting procedure is to authenticate the image and to execute it with help of Secure ROM Code services.

For an **HS Device** the ROM Code detects and parses the TOC. It searches for a main TOC item which filename must be one of ‘X-LOADER’, ‘2ND’, ‘MLO’, or ‘ULO’. After detection of the main TOC item the ROM Code starts the authentication phase as shown in Figure 30 and uses the TOC to locate the different items needed for the authentication phase.

The ROM Code searches for the mandatory Public Keys certificate and imports it to secure world. If an R&D certificate is present then the requested debug features are enabled accordingly. The Primary Protected Application is authenticated and imported into Secure RAM. The purpose of the last step is to authenticate the Initial SW.

If any of the secure items fails to authenticate then the ROM Code does not start the external code execution and branches to a dead loop (with the exception of the R&D certificate).

Figure 25-29. HS Image Authentication Process

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

25.3.11.2 Execution

The image is executed at the time the ROM Code performs the branch to the first executable instruction inside the Initial SW. For a **GP Device** in non-XIP the execution address is the first word after the GP header. On an **HS Device** the execution address is a parameter of the Initial SW certificate. The branch is performed in public ARM supervisor mode. The R0 register points to the Booting Parameters structure which contains various information about the booting execution. Table 25-40 details this structure.

Table 25-40. Booting Parameters Structure

Offset	Field	Size[bytes]	Description
00h	Reserved	4	Reserved

25.3.12 Wakeup

25.3.12.1 Overview

The device supports a comprehensive set of low-powered states to meet aggressive power budget requirements. The different low-power modes supported, from the lowest power consumption state to the highest power consumption state are

- RTC Only
- Deep Sleep 0
- Deep Sleep 1
- Deep Sleep 2
- Standby
- Active

Of these states, the ROM code come into the picture only in the first three, as the A8 registers (particularly the PC) are preserved in all the other states. So for these modes, on wake up, execution will resume from the next instruction following the WFI.

In the RTC only mode, the ROM code involvement is trivial, as a wakeup from the RTC only mode, for the ROM perspective, is indistinguishable from a power on reset. In Deep Sleep 0 and Deep Sleep 1 state, it is the ROM codes responsibility to detect wakeup has occurred, and branch to a user defined return address, rather than doing a full boot.

DRAFT ONLY

Copyright © 2011, Texas Instruments Incorporated

25.3.12.2 Wakeup Booting by ROM code

In this device, when the A8 is in OFF mode, execution begins from the reset vector on wakeup. As the reset vector lies in the ROM code, the ROM code is the first software entity that takes control of the A8 on a wakeup.

It must be noted here that in the device, in all the modes other than RTC only, the A8 internal SRAM and the L3 OCMC RAM are held in retention. This is a fundamental assumption of the ROM code. As the contents of these RAMs are not lost in the Deep Sleep modes, it is possible to return to a location in these memories.

This does away with the need of the ROM having to restore PLL and EMIF settings, which would have been needed if the ROM had to return to an DRAM address, as DRAM is held in self refresh. The job of dialing up the PLLs and restoring EMIF and other peripheral register values is the responsibility of the user code. The recommendation is that such restoration code be placed in the OCMC RAM so that the wakeup procedure is compatible between secure and non-secure devices.

In the past, having complex PLL and EMIF restore code in the ROM has made wakeup debugging very complicated. This has also traditionally been a source of many bugs, as the wakeup procedures are complicated and difficult to test exhaustively in pre-silicon.

The current architecture does away with these problems. The flow in the ROM on wakeup is kept simple and to the minimal. It only involves identifying that the reset reason is a Wakeup, and then branching to a return address, rather than proceeding with a full boot. This also helps in improving the time required to wakeup a system that is in Deep Sleep.

Figure 25-30. Wakeup Booting by ROM

25.3.13 Tracing

Tracing in the Public ROM Code consist in three 32 bit vectors for which each bit corresponds to a particular “way point” in the ROM Code execution sequence (see Table 25-4). Tracing vectors are initialized at the very beginning of the startup phase and updated all along the boot process.

There are two sets of tracing vectors. The first set is the current trace information (after cold or warm reset). The second set holds a copy of trace vectors collected at the first ROM Code run after cold reset. As a consequence after a warm reset it is possible to have visibility on the boot scenario that occurred during cold reset.

Table 25-41. Tracing Vectors

Trace vector	Bit #	Group	Meaning
1	0	General	Passed the public reset vector
1	1	General	Entered main function
1	2	General	Running after the cold reset
1	3	Boot	Main booting routine entered
1	4	Memory Boot	Memory booting started
1	5	Peripheral Boot	Peripheral booting started
1	6	Boot	Booting loop reached last device
1	7	Boot	GP header or HS TOC found
1	8	Boot	Reserved
1	9	Boot	Reserved
1	10	Peripheral Boot	Reserved
1	11	Peripheral Boot	Reserved
1	12	Peripheral Boot	Device initialized
1	13	Peripheral Boot	Asic Id sent
1	14	Peripheral Boot	Image received
1	15	Peripheral Boot	Peripheral booting failed

Table 25-41. Tracing Vectors (continued)

Trace vector	Bit #	Group	Meaning
1	16	Peripheral Boot	Booting Message not received (timeout)
1	17	Peripheral Boot	Image size not received (timeout)
1	18	Peripheral Boot	Image not received (timeout)
1	19	Reserved	Reserved
1	20	Configuration Header	CHSETTINGS found
1	21	Configuration Header	CHSETTINGS executed
1	22	Configuration Header	CHRAM executed
1	23	Configuration Header	CHFLASH executed
1	24	Configuration Header	CHMMCSD clocks executed
1	25	Configuration Header	CHMMCSD bus width executed
1	26	Reserved	Reserved
1	27	Reserved	Reserved
1	28	Reserved	Reserved
1	29	Reserved	Reserved
1	30	Reserved	Reserved
1	31	Reserved	Reserved
2	0	Companion chip	Reserved
2	1	Companion chip	Reserved
2	2	Companion chip	Reserved
2	3	Companion chip	Reserved
2	4	USB	USB connect
2	5	USB	USB configured state
2	6	USB	USB VBUS valid
2	7	USB	USB session valid
2	8	Reserved	Reserved
2	9	Reserved	Reserved
2	10	Reserved	Reserved
2	11	Reserved	Reserved
2	12	Memory Boot	Memory booting trial 0
2	13	Memory Boot	Memory booting trial 1
2	14	Memory Boot	Memory booting trial 2
2	15	Memory Boot	Memory booting trial 3
2	16	Memory Boot	Execute GP image
2	17	Peripheral Boot	Start authentication of peripheral boot image
2	18	Memory & Peripheral Boot	Jumping to Initial SW
2	19	Memory & Peripheral Boot	High Secure image not executed
2	20	Memory & Peripheral Boot	Start image authentication
2	21	Memory & Peripheral Boot	Image authentication failed
2	22	Memory & Peripheral Boot	Analyzing SpeedUp
2	23	Memory & Peripheral Boot	Speedup failed
2	24	Memory & Peripheral Boot	PPA authentication success
2	25	Memory & Peripheral Boot	PPA authentication failed
2	26	Memory & Peripheral Boot	R&D authentication success
2	27	Memory & Peripheral Boot	R&D authentication failed

Table 25-41. Tracing Vectors (continued)

Trace vector	Bit #	Group	Meaning
2	28	Memory & Peripheral Boot	Authentication procedure failed
2	29	Reserved	Reserved
2	30	Reserved	Reserved
2	31	Reserved	Reserved
3	0	Memory Boot	Memory booting device NULL
3	1	Memory Boot	Memory booting device XIP
3	2	Memory Boot	Memory booting device XIPWAIT
3	3	Memory Boot	Memory booting device NAND
3	4	Memory Boot	Memory booting device OneNAND
3	5	Memory Boot	Memory booting device MMCSD0
3	6	Reserved	Reserved
3	7	Memory Boot	Memory booting device MMCSD1
3	8	Reserved	Reserved
3	9	Reserved	Reserved
3	10	Memory Boot	Memory booting device EMIF LPDDR2-NVM
3	11	Reserved	Memory booting device SPI
3	12	Reserved	Reserved
3	13	Reserved	Reserved
3	14	Reserved	Reserved
3	15	Reserved	Reserved
3	16	Reserved	Peripheral booting device UART0
3	17	Reserved	Peripheral booting device UART1
3	18	Peripheral Boot	Peripheral booting device UART2
3	19	Reserved	Reserved
3	20	Peripheral Boot	Peripheral booting device USB
3	21	Peripheral Boot	Peripheral booting device USB ULPI
3	22	Peripheral Boot	Peripheral booting device GPGMAC0
3	23	Reserved	Peripheral booting device PCIe
3	24	Reserved	Peripheral booting device NULL
